1 ABSTRACT

2 Interest in behavioural realism has gradually led to the introduction of alternatives to random util-
3 ity models (RUMs) as a paradigm for representing choice behaviour, with notable interest, for
4 example, in random regret minimisation (RRM). These more general models continue to rely on a
5 framework where a single *value function* is calculated for each alternative in each choice setting,
6 and the choice probabilities are calculated by comparing these value functions across alternatives.
7 By contrast, research in mathematical psychology has used a more dynamic approach, where the
8 preference value of each alternative updates over time in a given situation while the decision maker
9 is deliberating about the choice to make. These *accumulator* models are well suited to accom-
10 modating a variety of context effects, and have been shown to give good performance for data
11 collected in laboratory-based settings. The present paper considers two such accumulator models,
12 namely decision field theory (DFT) and the multi-attribute linear ballistic accumulator (MLBA),
13 and addresses limitations that have prevented their use in travel behaviour research. The method-
14 ological additions include the ability to capture the influence of socio-demographics, the presence
15 of underlying preferences for specific alternatives, and/or the representation of attributes that have
16 opposite effects on choice probabilities. We develop what we believe to be the first in-depth simul-
17 taneous comparison of DFT and MLBA with typical discrete choice models, and test both DFT
18 and MLBA on a revealed preference dataset. We find that each model outperforms typical RUM
19 and RRM implementations for both in-sample estimation and out-of-sample prediction, including
20 in a large scale simulation experiment.

1 1. INTRODUCTION

2 Whilst mainstream choice modelling has firm economic foundations (McFadden, 1974), the mod-
3 elling of decision-making behaviour in other fields has been characterised by very different aims
4 and objectives. Since work in the 1970s (Tversky, 1972; Tversky and Kahneman, 1973; Tver-
5 sky, 1977), the field of behavioural economics has considered choice from an economic viewpoint
6 whilst simultaneously demonstrating that decision-makers are subject to biases, heuristics and con-
7 text effects that result in choices that are not the most likely under traditional choice models.
8 Choice modellers have long had an interest in increasing the behavioural realism of their models,
9 with recent methodological advances aimed at incorporating alternative behavioural ideas such as
10 random regret minimisation (RRM) (Chorus et al., 2008; Chorus, 2010), heuristics (Swait, 2001),
11 satisficing (González-Valdés and Ortúzar, 2017) and the incorporation of information processing
12 strategies such as attribute non-attendance (for a detailed review, see Hensher (2010)).

13 Moving away from the traditional random utility maximisation (RUM) framework however
14 entails a number of disadvantages, most notably an inability to easily use the results in welfare
15 analysis (Hess et al., 2018). This means that careful consideration is required before we move
16 to alternative models. In this context, the question then arises whether, if we are willing to move
17 away from RUM, we should move to models that are substantially different from it, rather than still
18 staying within a logit framework as is the case for random regret minimisation. This observation
19 leads us to look further afield in the present paper, and in particular at work in mathematical psy-
20 chology, where researchers have developed mathematical and computational models that represent
21 context effects such as attraction, compromise and similarity (Roe et al., 2001; Trueblood et al.,
22 2013b; Noguchi and Stewart, 2014) as well as decision-making under time pressure (Busemeyer
23 and Townsend, 1993).

24 Two models in particular have attracted substantial attention in mathematical psychology,
25 namely Decision Field Theory (DFT) (Busemeyer and Townsend, 1992, 1993; Roe et al., 2001)
26 and the multi-attribute linear ballistic accumulator (MLBA) (Trueblood et al., 2013a, 2014). These
27 models also represent the choice between mutually exclusive alternatives but differ from more
28 traditional discrete choice models in one specific dimension. RUM and RRM models are charac-
29 terised by their utility and regret functions respectively, which are used to calculate a *single value*
30 *function* for each alternative, where comparison of this across alternatives then leads to probabili-
31 ties of a given alternative being chosen. This value function is calculated once per choice situation.
32 On the other hand, DFT and MLBA are members of a broad family of *accumulator* models, where
33 the *cumulative preference* value for an alternative in a single choice context is updated (linearly in
34 MLBA, stochastically in DFT) over time.

35 Under DFT, the decision maker updates his/her preference for given alternatives by repeated
36 comparisons between them, considering one attribute at a time, where the attribute values of the
37 alternatives in that situation remain constant across these comparisons. Under MLBA, a ‘drift
38 rate’ is generated at the outset for each alternative; this then drives the updating of the strength of
39 preference of each alternative within the given choice context.

40 At first, this description of the models might seem similar to choice modelling work that has

1 looked at preferences evolving over a sequence of choices, such as models incorporating value
2 learning (McNair et al., 2012), state dependence (Bruno et al., 2015) or dynamic discrete choice
3 models (Liu and Cirillo, 2018). However, *accumulator* models are structures for internal prefer-
4 ence accumulation at the level of every single choice, not models that accumulate evidence over a
5 sequence of choices. The accumulation models thus capture the mental deliberation from the time
6 a particular choice is faced (or stated choice scenario is presented) to the point where the choice is
7 made. The preferences are reset after that, so that the accumulation effect is not carried over to the
8 next choice task, i.e. the accumulation made when considering choice set k does not affect choice
9 set $k + 1$ although such extensions are possible too if warranted by the choice context.

10 As is common with work in mathematical psychology, much of the focus of using DFT and
11 MLBA has been on testing for the presence of specific behavioural phenomena in data collected in
12 lab-based experiments, with little or no focus on prediction or on using data from complex choice
13 scenarios. However, the way in which preferences evolve over time and their inherent ability to
14 accommodate a range of what economists might call behavioural anomalies make these models
15 potentially very appealing for studying more complex decisions, including travel behaviour. This
16 statement is not completely without exceptions. For example, Hawkins et al. (2014) applied the
17 linear ballistic accumulator (LBA, Brown and Heathcote 2008), a precursor to MLBA, to consumer
18 attitudes and patient preferences; Hawkins et al. (2019) provided LBA applications to multi-period
19 stated preference for consumer products; and Berkowitsch et al. (2014) applied DFT to consumer
20 choices for products such as computers, cameras and racing bicycles. In key comparisons against
21 *traditional* choice models, DFT in particular has been found to outperform random utility and
22 random regret based models (e.g. Berkowitsch et al. 2014; Hancock et al. 2018).

23 Another distinction is that in mathematical psychology, accumulator models are typically used
24 to jointly model the outcome of the choice process and the time it takes to reach that decision. In
25 a traditional choice modelling context, it is the former that is of key interest, and this thus calls for
26 further investigation of the potential advantages of these models in the context of data with choice
27 outcomes only (as opposed to additional information on decision time), as well as investigating any
28 mathematical adaptations required in such cases. In this context, it is worth noting that while some
29 comparisons of MLBA and DFT have concluded that response time data is required to clearly dif-
30 ferentiate the models (Evans et al., 2019b), applications within mathematical psychology typically
31 do not study alternatives that are evaluated in qualitatively different ways by different participants
32 and also tend to present tasks in which there are correct/incorrect answers. The work in this pa-
33 per, by contrast, considers *subjective preferential choice* data, in which the complicated evaluation
34 of alternatives makes choice-only data sufficiently rich to demonstrate differentiation of the pre-
35 dictive capabilities of traditional choice models and the accumulation models from mathematical
36 psychology.

37 In a travel behaviour context, MLBA has thus far not been used, while the use of DFT to
38 date has been limited due to the computational limitations (Otter et al., 2008). Our previous work
39 on DFT has focused on methodological improvements that have made it possible to rigorously
40 test DFT against typical choice models (Hancock et al., 2018). This motivates us to investigate
41 the suitability of MLBA in modelling travel behaviour as well, as it has been found to outperform
42 DFT in applications in the mathematical psychology literature (Trueblood et al., 2014; Cohen et al.,

1 2017; Turner et al., 2018). Furthermore, there has been increasing attention in transport and choice
2 modelling in general on best-worst datasets (Giergiczny et al., 2013; Rose, 2014; Hawkins et al.,
3 2019) and research in mathematical psychology has shown that linear ballistic accumulators, with
4 each alternative having a mean drift rate equal to an alternative-specific constant, perform well for
5 these datasets (Hawkins et al., 2014).

6 Beyond simply comparing the two structures, we make a number of methodological improve-
7 ments to both DFT and MLBA to facilitate their application to rich multi-alternative multi-attribute
8 preferential choice datasets. The key contribution relates to allowing analysts to use DFT with
9 attributes that have opposite effects on choice probabilities, and where this directionality is not
10 known a priori. Previously, DFT models included ‘attention weights’ which could be used to cap-
11 ture the relative importance of attributes. As these weights must be positive (and sum to one), a
12 priori knowledge is required as to whether an attribute has a positive (e.g. comfort of journey) or
13 negative (e.g. cost) impact on the likelihood of an alternative being chosen. This is particularly
14 an issue for consumer attributes which some decision-makers may like and others dislike, such as
15 the size of a car; we handle such effects with attribute-specific scaling coefficients, meaning that
16 such a priori knowledge is no longer required. We show that these coefficients can also be added
17 to MLBA to capture the relative importance as well as the directionality of different attributes, a
18 feature not typically accounted for in standard MLBA implementations. Further improvements
19 include the ability to capture the influence of socio-demographics and the presence of underlying
20 preferences for specific alternatives, in a manner equivalent to alternative specific constants in typ-
21 ical discrete choice models. We also look in detail at identification issues for both models, and
22 present a number of empirical tests to help inform future applications.

23 In our empirical work, we offer what we believe to be the first in-depth simultaneous compar-
24 ison of DFT and MLBA with typical discrete choice models, and also for the first time test both
25 DFT and MLBA on a revealed preference dataset. We find that each model outperforms RUM and
26 RRM implementations for both estimation and out-of-sample prediction across our datasets, and
27 in a large scale simulation experiment.

28 The remainder of this paper is organised as follows. In the next section, we first provide an
29 overview of the two models in their current form before presenting our various methodological
30 improvements. This is followed by our empirical work on stated choice and revealed preference
31 data, before some further tests on simulated data. The final section summarises the findings and
32 presents some directions for future research.

33 2. METHODOLOGY: CONTRASTING AND IMPROVING MODELS FROM MATHE- 34 MATICAL PSYCHOLOGY

35 In this section, we first provide an introduction to accumulator models. We then present state-of-
36 the-art implementations before making methodological improvements for both DFT and MLBA.

1 2.1. Introduction to accumulator models

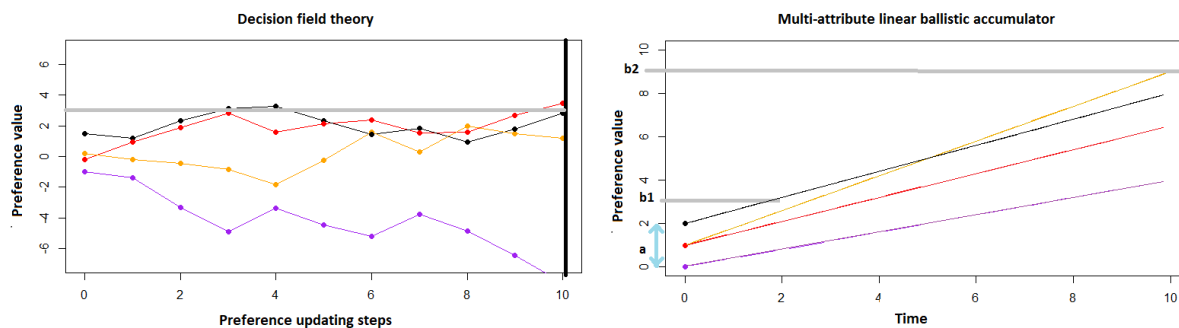

2 Since the introduction of the drift diffusion model (Ratcliff, 1978), many different variations
3 of accumulation models have been developed by mathematical psychologists (Busemeyer and
4 Townsend, 1992; Usher and McClelland, 2001; Krajbich et al., 2012). Some of these accumu-
5 lation models fall into the more specific category of sequential sampling models (see Busemeyer
6 et al. (2019) for a review of these models). The idea of a sequential sampling model is that pref-
7 erences for alternatives update over time depending on what information is being considered. An
8 individual may consider, for example, cost, before then considering travel time. They might make
9 comparisons across alternatives sequentially or randomly. By contrast, mainstream choice models
10 such as random utility or random regret models construct just a single one-off preference or util-
11 ity value for each alternative given a set of attribute values and then use those values, with error
12 components, to calculate choice probabilities. Critically, sequential sampling models and more
13 generally accumulation models instead assume that these preferences change over the course of
14 the deliberation process whilst the decision-maker is choosing an alternative (even if the attributes
15 of the alternatives stay the same). As already highlighted in the introduction, this preference accu-
16 mulation is internal and happens at the level of every single choice, i.e. it is not an accumulation
17 over a sequence of choices. Consequently, we can contrast the models with typical discrete choice
18 structures.

19 Accumulator models aim to ‘understand the motivational and cognitive mechanisms that
20 guide the deliberation process involved in decisions’ (Busemeyer and Townsend, 1993). The
21 assumed mechanisms have subsequently been shown to resemble those in neural circuits. For
22 example, Gold and Shadlen (2000) found that during a motion perception task, there was an accu-
23 mulation of sensory evidence in the neural circuits of a monkey’s brain, creating a behavioural re-
24 sponse when the appropriate amount of information had been received. Furthermore, accumulator
25 models have been developed that explain/describe context effects (Hotaling et al., 2010; Trueblood
26 et al., 2014), capture risky choice behaviour (Busemeyer and Townsend, 1993; Stewart and Simp-
27 son, 2008) and can predict preference reversals (Diederich, 2003). Additionally, dynamic models
28 provide a naturalistic method for the modelling of decision making in dynamic choice settings
29 (Holmes et al., 2016).

30 One popular model from mathematical psychology that can easily be compared to traditional
31 discrete choice models is decision field theory (DFT), first introduced by Busemeyer and Townsend
32 (1992, 1993) and first operationalised in the context of travel behaviour by Hancock et al. (2018).
33 In a DFT model, preference values for the alternatives update stochastically over time. At each
34 moment, a single attribute is compared across alternatives and a valence (momentary preference)
35 is added to the preference value for each alternative. At some point, the decision-maker comes to a
36 conclusion, either as one of the alternatives reaches some threshold (similar to satisficing Kaufman,
37 1990; Schwartz et al., 2002; González-Valdés and Ortúzar, 2017) or as an external cue forces the
38 decision-maker to make a choice, in which case the decision-maker chooses the alternative with the
39 highest preference value at that moment. As an example, the left panel in Figure 1 demonstrates
40 that different alternatives may be chosen depending on which threshold is used. The alternative
41 that first reaches the internal threshold value is not the one that first reaches the time threshold.
42 Here, it should be noted that the value that evolves over comparison is a *preference value*, rather

1 than a probability, where the latter is calculated from the expectation of the former, a point we will
 2 return to later. The horizontal axis is measured in *preference updating steps*, which relate to the
 3 number of comparisons between alternatives, on each occasion using one attribute.

FIGURE 1 : An example decision process under both accumulation models

4 The linear ballistic accumulator model (Brown and Heathcote, 2008) and its multi-attribute
 5 version MLBA (Trueblood et al., 2013a, 2014) have a similar accumulation process for the prefer-
 6 ence of alternatives, but, in contrast with DFT, the updating is not stochastic. Instead, under LBA,
 7 decision-makers start with some random amount of initial ‘evidence’ for each alternative, and a
 8 random value of a drift rate, with the evidence in each ‘accumulator’ then increasing linearly with
 9 that sampled rate until one of the accumulators (alternatives) reaches a threshold. This sampled
 10 rate depends on the drift rate distributional and functional form, meaning that the preference values
 11 for each accumulator grow linearly at some drift rate dependent on the attribute levels of the alter-
 12 native. A particular form for the drift rates (detailed in Section 2.3) give the MLBA. Depending on
 13 the level of the threshold, different alternatives may be chosen. This is demonstrated in the right
 14 panel of Figure 1, in which each alternative (accumulator) starts with some random initial value,
 15 assumed to be in an interval a , and a different alternative is chosen when the threshold value is b_1
 16 than when it is b_2 . The linear drift rates imply that, unlike in DFT, once the alternative with the
 17 largest (sampled) drift rate value ‘gains the lead’ there is no way for another alternative to recover
 18 and be chosen. Whilst this would not be the case with a non-linear specification, the current model
 19 is specifically linear to allow for simple calculation of the probabilities of alternatives. As with
 20 DFT, the value that evolves over time is a preference value, while the horizontal axis in Figure 1
 21 now relates to actual time, given that no additional comparisons are made.

22 The mathematics underlying MLBA and DFT is vastly different. LBA was specifically de-
 23 signed such that it is ‘simple’ (Brown and Heathcote, 2008) and mathematically tractable, with
 24 MLBA subsequently developed such that it can also accurately capture and predict context effects.
 25 The simpler mathematical nature means that the probabilities of alternatives can easily be calcu-
 26 lated from a combination of normal and uniform cumulative density functions (see Section 2.3 for
 27 a full description of MLBA).

28 It may be noted that there are numerous other accumulation models from mathematical psy-
 29 chology that seek to explain choice processes and predict choices. However, not all are currently
 30 suitable for transitioning into applied choice modelling. Given the complex nature of transport
 31 datasets, for example in terms of number of alternatives, even simple implementations will impose

1 large computational costs. This is then further increased if analysts wish to add random hetero-
 2 geneity in preferences, and models from mathematical psychology thus need to be efficient to run
 3 at a basic level if they are to compete. This means that models that do not have analytical solutions
 4 for calculating the choice probabilities will likely not be suitable options. For example, the leaky
 5 competing accumulator model (LCA, [Usher and McClelland 2001](#)) would require two levels of
 6 simulation in order to incorporate random parameters. Requirements for computer intensive sim-
 7 ulation are also issues for the associative accumulation model ([Bhatia, 2013](#)) and the attentional
 8 drift diffusion model ([Krajbich et al., 2012](#)).

9 **2.2. Decision field theory (DFT)**

10 In this section, we first look at the existing implementation of DFT before making a number of
 11 methodological improvements and finally turning to identification issues.

12 *2.2.1. Existing implementation*

13 *2.2.1.1 Theoretical model*

14 Decision field theory, as an accumulator model, has preference values for each alternative that
 15 update over a number of preference updating steps¹ (see left panel in [Figure 1](#)). For decision-maker
 16 n in choice task (set) s , the vector of preferences after τ preference updating steps is denoted $\mathbf{P}_{ns,\tau}$
 17 and is of size J_n where J_n is the number of alternatives in the choice set CS_{ns} . The preferences then
 18 update according to:

$$\mathbf{P}_{ns,\tau+1} = S_{ns} \cdot \mathbf{P}_{ns,\tau} + \mathbf{V}_{ns,\tau+1}, \quad (1)$$

19 where the previous values, $\mathbf{P}_{ns,\tau}$, are multiplied by a feedback matrix, S_{ns} , and a valence vector
 20 $\mathbf{V}_{ns,\tau+1}$ is added. It is worth noting here that DFT is often formulated as a linear difference equation
 21 with step size h (see, for example, [Busemeyer and Diederich \(2002\)](#)). We follow [Roe et al. \(2001\)](#)
 22 in explicitly using step sizes of $h = 1$. This means that analytical solutions for calculating the
 23 probability of choosing each alternative still exist, whilst avoiding the fact that different step sizes
 24 (values of h) can result in different outcomes ([Evans et al., 2019b](#)). The feedback matrix has two
 25 parameters that influence the existence and/or strength of attraction, similarity and compromise
 26 effects ([Roe et al., 2001](#); [Hotaling et al., 2010](#); [Noguchi and Stewart, 2014](#)), and is defined as:

$$S_{ns} = I_{ns} - \phi_2 \times \exp(-\phi_1 \times D_{ns}^2) \quad (2)$$

27 where ϕ_1 is a sensitivity parameter, ϕ_2 is a memory parameter, I_{ns} is the identity matrix of size
 28 $J_n \times J_n$ and D_{ns} is the distance between alternatives measured with respect to the attribute-levels.
 29 Whilst the relative importance of the different attributes can be taken into account with a psycho-
 30 logical distance function ([Hotaling et al., 2010](#)) and work on new distance functions is possible
 31 (e.g. [Berkowitsch et al., 2015](#)), the Euclidean distance between the attributes can also be used for
 32 simplicity ([Qin et al., 2013](#)). The sensitivity parameter, ϕ_1 , affects how much the alternatives com-
 33 pete with each other. Values very close to zero results in the distance between the attributes of

¹Note that whilst it is possible that separate choice tasks could be linked through parameters controlling for learning effects, all of the DFT models in this paper assume that all choice tasks are entirely independent of each other to make them comparable with the RUM and RRM models without state-dependence.

1 alternatives becoming less important, whereas higher values result in more competition between
 2 similar alternatives. The memory parameter (also known as the decay parameter) determines the
 3 relative importance of attributes considered towards the end of the decision process relative to
 4 those considered at the start. A value of one results in zeros on the diagonals of the feedback ma-
 5 trix, which results in the preference already accumulated becoming irrelevant. As this value tends
 6 towards zero, the importance of the already accumulated preference increases.

7 DFT assumes that, at each preference updating step, the decision-maker compares a single
 8 attribute across all of the alternatives. This results in a random valence vector at step τ , $\mathbf{V}_{ns,\tau}$,
 9 which can be calculated as:

$$\mathbf{V}_{ns,\tau} = C_{ns} \cdot M_{ns} \cdot \mathbf{W}_{ns,\tau} + \boldsymbol{\varepsilon}_{ns,\tau} \quad (3)$$

10 where C_{ns} is a contrast matrix used to rescale the values such that they total zero, M_{ns} is the
 11 matrix of attribute values dependent on the specific choice task and $\mathbf{W}_{ns,\tau} = [0..1..0]^t$ with the k^{th}
 12 entry, i.e. $\mathbf{W}_{ns,\tau,k} = 1$ if and only if attribute x_k is the attribute being attended to by the decision-
 13 maker at preference updating step τ . A DFT model thus typically estimates a weight, w_k , for the
 14 likelihood of attribute x_k being the single attribute attended to at a given step, where $\sum_k w_k = 1$.
 15 There is also a random error vector, $\boldsymbol{\varepsilon}_\tau = [\varepsilon_1.. \varepsilon_{J_n}]^t$, with $\varepsilon_i \sim N(0, s)$, distributed identically and
 16 independently across alternatives, steps, individuals and choice tasks. This allows for flexibility in
 17 the range of probability values that DFT predicts. This is in essence an error or noise parameter
 18 (Roe et al., 2001), for which higher values would be expected for more complex decision-making
 19 tasks (Hotelling et al., 2010).

20 2.2.1.2 Calculating choice probabilities

21 Under a DFT model, at the conclusion of the deliberation process, the alternative that is chosen
 22 is the one with the greatest preference value, regardless of whether the individual stopped deliber-
 23 ating due to a time threshold or due to the preference value for one of the alternatives reaching a
 24 preference threshold. Given that most choices do not have a strict time threshold, some applica-
 25 tions of DFT calculate the probability for each alternative's preference value reaching a particular
 26 threshold first (see examples in Hotelling et al. (2010) and Turner et al. 2018). Given that this prob-
 27 ability has no closed-form solution for more than two alternatives, we rely on Roe et al. (2001)'s
 28 method to calculate a related set of choice probabilities - namely, the probability for each alter-
 29 native being chosen after τ preference accumulation steps. This uses the expected value and the
 30 covariance of the preference values ($\boldsymbol{\xi}_{ns,\tau}$ and $\Omega_{ns,\tau}$) and results in the stochastic variation being
 31 averaged out such that the choice probabilities can be calculated without the computationally heavy
 32 simulation that is required for DFT applications by, for example, Turner et al. (2018); Evans et al.
 33 (2019b).

34 To calculate the expected value of the preference values, we must first expand Equation 1,
 35 which results in:

$$\mathbf{P}_{ns,\tau} = \sum_{r=0}^{\tau-1} S_{ns}^r \cdot \mathbf{V}_{ns,\tau-r} + S_{ns}^\tau \cdot \mathbf{P}_{ns,0} \quad (4)$$

36 where $\mathbf{P}_{ns,0} = [\delta_{ns,1}, \delta_{ns,2}, \dots, \delta_{ns,J_n}]$ is the initial preference vector, with values $\delta_{ns,i} \in \mathbb{R}$. This is
 37 often assumed to be a vector of zeros (Busemeyer and Diederich, 2002) but can also be used to

1 capture underlying preferences for different alternatives (Hancock et al., 2018), where $\delta_{ns,i} = \delta_i$,
 2 i.e. an estimated parameter that is fixed across individuals and choice tasks.

3 The attribute weights w_k are stationary, therefore $\mathbf{W}_{ns,\tau}$ can be considered a stationary stochas-
 4 tic process. This means that $\mathbf{V}_{ns,\tau}$ is also a stationary stochastic process with mean $E[\mathbf{V}_{ns,\tau}]$
 5 and a variance covariance matrix given by $Cov[\mathbf{V}_{ns,\tau}]$. We let $\boldsymbol{\varepsilon}_{ns,\tau}$ vary according to a nor-
 6 mal distribution with mean zero and variance $\sigma_{\boldsymbol{\varepsilon}}^2$. Given that $\boldsymbol{\mu}_{ns} = E[\mathbf{V}_{ns,\tau}]$, it can be calcu-
 7 lated as $\boldsymbol{\mu}_{ns} = C_{ns} \cdot M_{ns} \cdot \mathbf{w}$, where \mathbf{w} is a vector containing the attribute attention weights, w_k ,
 8 which corresponds to the probability of each of the attributes being considered. We also have
 9 $Cov[\mathbf{V}_{ns,\tau}] = \Phi_{ns} = C_{ns} \cdot M_{ns} \cdot \Psi_{ns} \cdot M'_{ns} \cdot C'_{ns} + \sigma_{\boldsymbol{\varepsilon}}^2 \cdot I$, where $\Psi_{ns} = Cov[\mathbf{W}_{ns,\tau}]$ and I is the identity
 10 matrix (C_{ns} and M_{ns} are matrices of constants). We can then calculate the expected value and the
 11 covariance of $\mathbf{P}_{ns,\tau}$. With S_{ns} being a constant, $E[\mathbf{P}_{ns,\tau}]$ reduces to:

$$E[\mathbf{P}_{ns,\tau}] = \boldsymbol{\xi}_{ns,\tau} = \sum_{r=0}^{\tau-1} S_{ns}^r \cdot \boldsymbol{\mu}_{ns} + S_{ns}^{\tau} \cdot \mathbf{P}_{ns,0} \quad (5a)$$

$$= (I_{ns} - S_{ns})^{-1} (I_{ns} - S_{ns}^{\tau}) \cdot \boldsymbol{\mu}_{ns} + S_{ns}^{\tau} \cdot \mathbf{P}_{ns,0} \quad (5b)$$

12 We can also now calculate the covariance of the preference values:

$$Cov[\mathbf{P}_{ns,\tau}] = \Omega_{ns,\tau} = Cov \left[\sum_{r=0}^{\tau-1} S_{ns}^r \cdot \mathbf{V}_{ns,\tau-r} + S_{ns}^{\tau} \cdot \mathbf{P}_{ns,0} \right] \quad (6a)$$

$$= \sum_{r=0}^{\tau-1} \left[S_{ns}^r \cdot \Phi_{ns} \cdot S_{ns}^{r'} \right] \quad (6b)$$

13 The resulting calculations are complex, but as shown in our earlier work (Hancock et al., 2018),
 14 we can further simplify $Cov[\mathbf{P}_{ns,\tau}]$ such that we can avoid the summation. We replace the feedback
 15 matrices with a matrix Z_{ns} of size $J_n^2 \times J_n^2$ (where J_n is the number of alternatives) and reshape Φ_{ns}
 16 (with entries $p_{i,j}$) into a column matrix, $\bar{\Phi}_{ns}$:

$$Z_{ns} = \begin{bmatrix} z_{1,1} & z_{1,2} & \cdots & z_{1,J_n^2} \\ z_{2,1} & z_{2,2} & \cdots & z_{2,J_n^2} \\ \vdots & \vdots & \ddots & \vdots \\ z_{J_n^2,1} & z_{J_n^2,2} & \cdots & z_{J_n^2,J_n^2} \end{bmatrix}, \bar{\Phi}_{ns} = \begin{bmatrix} p_{1,1} \\ p_{1,2} \\ \vdots \\ p_{1,J_n} \\ p_{2,1} \\ \vdots \\ p_{J_n,J_n} \end{bmatrix} \quad (7)$$

17 As S_{ns} is a symmetric matrix, we can then define Z_{ns} by setting it as the Kronecker product of S_{ns}
 18 with itself: $z_{i,j} = S_{(i \bmod J_n, j \bmod J_n)} \cdot S_{([i/J_n], [j/J_n])}$. The calculation of the covariance of $\mathbf{P}_{ns,\tau}$ now
 19 simplifies to:

$$Cov[\mathbf{P}_{ns,\tau}] = \mathbf{\Omega}_{ns,\tau} = \sum_{r=0}^{\tau-1} \left[S_{ns}^r \cdot \Phi_{ns} \cdot S_{ns}^{r'} \right] \quad (8a)$$

$$= \sum_{r=0}^{\tau-1} \left[Z_{ns}^r \cdot \overline{\Phi}_{ns} \right] \quad (8b)$$

$$= (\mathbf{I}_{ns} - \mathbf{Z}_{ns})^{-1} (\mathbf{I}_{ns} - \mathbf{Z}_{ns}^{\tau}) \overline{\Phi}_{ns} \quad (8c)$$

1 These succinct forms for $\xi_{ns,\tau}$ and $\mathbf{\Omega}_{ns,\tau}$ mean that we can now calculate the probability with which
 2 each alternative is chosen. On the basis of the multivariate central limit theorem, $\mathbf{P}_{ns,\tau}$ converges
 3 to the multivariate normal distribution (Roe et al., 2001). This means that if a time (step) threshold
 4 is reached, the choice probability of choosing alternative j from the set CS_{ns} of J_n alternatives at
 5 step τ is:

$$Prob \left[\mathbf{P}_{ns,\tau} [j] = \max_{i \in CS_{ns}} \mathbf{P}_{ns,\tau} [i] \right] = \int_{\mathbf{X}_{ns,\tau} > 0} \exp \left[-(\mathbf{X}_{ns,\tau} - \mathbf{\Gamma}_{ns,\tau})' \Lambda_{ns,\tau}^{-1} (\mathbf{X}_{ns,\tau} - \mathbf{\Gamma}_{ns,\tau}) / 2 \right] / (2\pi |\Lambda_{ns,\tau}|^{0.5}) d\mathbf{X} \quad (9)$$

6 with $\mathbf{X}_{ns,\tau} = [\mathbf{P}_{ns,\tau} [j] - \mathbf{P}_{ns,\tau} [1], \dots, \mathbf{P}_{ns,\tau} [j] - \mathbf{P}_{ns,\tau} [J_n]]'$, the set of differences between the pref-
 7 erence for the j^{th} element and the preferences for each respective element $i \in C_{ns}$, $i \neq j$. Then we
 8 have $\mathbf{\Gamma}_{ns,\tau} = L_{ns} \cdot \xi_{ns,\tau}$ and $\Lambda_{ns,\tau} = L_{ns} \cdot \mathbf{\Omega}_{ns,\tau} \cdot L_{ns}'$ where

$$L_{ns} = \begin{bmatrix} 1 & -1 & 0 & \dots & \dots & 0 \\ 1 & 0 & -1 & \ddots & & \vdots \\ 1 & \vdots & \ddots & \ddots & \ddots & \vdots \\ 1 & \vdots & & \ddots & -1 & 0 \\ 1 & 0 & \dots & \dots & 0 & -1 \end{bmatrix} \quad (10)$$

9 with L_{ns} being a matrix constructed with a column vector of 1s and a negative identity matrix of
 10 size $J_n - 1$ where J_n is the number of alternatives. The column vector of 1s is placed in the j^{th}
 11 column where j is the chosen alternative.

12 2.2.2. New developments

13 2.2.2.1 Scaling of DFT

14 In a typical linear additive RUM or RRM model, changing the units of a single attribute only
 15 affects the parameter for that attribute. For example, changing the unit of travel time from minutes
 16 to hours results in the corresponding marginal utility component being multiplied by 60, with no
 17 impact on other parameters.

18 DFT on the other hand is scale-variant (Busemeyer and Diederich, 2002; Trueblood et al.,
 19 2013a), where the requirements that the attribute weights sum to one ($\sum_k w_k = 1$) means that a
 20 change in the scale for one attribute, unless accounted for, might be incorrectly interpreted as a

1 change in the distribution of the attribute weights. The following material illustrates how to extend
 2 DFT (and related models) so that importance weights are unchanged by such scale changes (for
 3 the proof of how the new scaling parameters result in DFT become scale-invariant, please see
 4 Appendix C). Suppose we are studying a choice situation where the two attributes are cost and
 5 time, with cost measured in £ sterling and time measured in hours. Let c_\pounds (resp., t_h) be the cost in
 6 £ (resp., duration in hours) of a particular choice alternative, and assume that we have been able to
 7 show that its value is given by:

$$(0.6)c_\pounds + (0.4)t_h, \quad (11)$$

8 where the coefficient (0.6) [resp., (0.4)] measures the importance of cost in £ (resp., time in hours)
 9 to the decision maker.² The above formulation is fine so long as one continues to work with cost
 10 measured in £ and time measured in hours, but will lead the researcher astray if they want to change
 11 their measurements to cost measured in Euros and time measured in minutes. Rather than go down
 12 that erroneous path, we simply note that there are implicit parameters in Equation 11 that indicate
 13 that c (cost) is measured in £ and t (time) is measured in hours. We make those parameters explicit
 14 by rewriting Equation 11 as:

$$(0.6)k_{c_\pounds}c_\pounds + (0.4)k_{t_h}t_h, \quad (12)$$

15 where $k_{c_\pounds} = k_{t_h} = 1$. Such parameters have various names in the (measurement) literature, including
 16 *dimensional parameters* (Luce, 1962) and *scale-dependent parameters* (Luce et al. (1990), Section
 17 22.2.4 and page 308). The advantage - in fact, conceptual necessity - of including such parameters
 18 is that if we now change our measurement scales - say, from £ to Euros and from hours to minutes
 19 - then the importance weights will remain the same (as they should), and the (scale) parameters for
 20 cost and time change. For example, with $1\pounds = 1.18$ Euro and one hour equal 60 minutes, Equation
 21 11 becomes:

$$(0.6)k_{c_E}c_E + (0.4)k_{t_m}t_m, \quad (13)$$

22 where c_E (resp. t_m) is the cost in Euros (resp., time in minutes) and $k_{c_E} = \frac{1}{1.18}$ and $k_{t_m} = \frac{1}{60}$.

23 It is possible that scaling functions can be applied to the attributes before they enter Equation
 24 3 (see Section 3.5 or also the ‘scaling of attributes’ section of Hancock et al. (2018)). However,
 25 it is not clear which method should be used a priori, thus we instead define a new scaling method
 26 which translates attribute values into ‘subjective’ values directly. This is achieved by multiplying
 27 the values by a vector of attribute-specific scaling coefficients,³ β_{DFT} , with properties paralleling
 28 the scale-dependent parameters of Equations 11 and 12. This results in the following function for
 29 the random valence vector at step τ (dropping the indices for individual and choice task), \mathbf{V}_τ :

$$\mathbf{V}_\tau = \mathbf{C} \cdot \mathbf{M} \cdot \beta \cdot \mathbf{W}_\tau + \boldsymbol{\varepsilon}_\tau \quad (14)$$

30 where \mathbf{M} is the original attribute matrix, but with each attribute multiplied by its corresponding
 31 scaling value from the diagonal matrix β , which has the set of estimated scaling values, β_{DFT} ,
 32 on the diagonal entries. With this specification, a decision-maker still attends to a given attribute
 33 at random in a given evaluation. In \mathbf{W}_t , as before, one element is equal to 1 with all others 0.

²See Marley et al. (2008), Section 6 for a discussion of the conceptual and practical issues in obtaining such (separable) information on importance and value.

³We use the term β_{DFT} here as these values correspond to the marginal utility components, β , of RUM, but they cannot be used equivalently in, for example, value of travel time calculations.

1 Furthermore, we also multiply the attributes by their corresponding scaling coefficients before they
 2 are used to estimate the distances between alternatives in the feedback matrix (D_{ns} in Equation 2).
 3 The distance between alternatives i and j is thus:

$$D_{ns,ij}^2 = \sum_{k=1}^K (\beta_k \cdot (x_{ns,i,k} - x_{ns,j,k}))^2 \quad (15)$$

4 with $x_{ns,k,i}$ the objective value for the k^{th} attribute for alternative i and β_k the relative importance
 5 of attribute k . The addition of these scaling parameters results in three possible versions of DFT
 6 models:

- 7 1. A general model incorporating both attribute attribute-specific scaling coefficients and at-
 8 tribute weights.
- 9 2. A model with attribute-specific scaling coefficients only. The attribute weights, w_k , are not
 10 estimated, with the modeller simply fixing the weights equal to $1/K$ where K is the number of
 11 attributes. This implies that each attribute is just as likely to be attended to at each preference
 12 updating step. Whilst this would be unlikely to be the case in the presence of eye-tracking
 13 data, it is a reasonable assumption a priori with choice-only data.
- 14 3. A model with attribute weights only. The scaling coefficients are all fixed to a value of 1.
 15 This is of course equivalent to the original multialternative DFT specification by [Roe et al.](#)
 16 (2001).

17 We empirically test these different versions against each other and alternative scaling methods in
 18 Section 3.5. The addition of attribute scaling coefficients to DFT results in a number of important
 19 benefits.

- 20 • First, the revised version of DFT is no longer scale-variant. Changing the unit of travel time
 21 from minutes to hours will now impact the estimate for the travel time scaling coefficient
 22 only. This means that for each marginal utility coefficient in a RUM model (or a marginal
 23 regret coefficient in a RRM model), there is a corresponding attribute scaling coefficient in
 24 the DFT model. This allows us to make comparisons across the different models in terms of
 25 relative importance of different attributes.
- 26 • Second, the attributes are now adjusted accordingly for their relative importance *before* they
 27 enter the feedback matrix, meaning that we can calculate an appropriate psychological dis-
 28 tance by simply taking Euclidean distances in the calculation of the feedback matrix. Conse-
 29 quently, we do not need a separate ‘dominance’ parameter as defined by [Berkowitsch et al.](#)
 30 (2015) to take the relative importance of the attributes into account.
- 31 • Third, we now separate out the effects of the frequency of considering individual attributes,
 32 through the weights, and the importance of different attributes in changing the preference
 33 values, through the scaling parameters. Conceptually, only the latter should be influenced by
 34 changes in units.

- 1 • Fourth, an even more important benefit of the proposed scaling approach relates to the pos-
 2 sibility of attributes having opposite impacts on probabilities, i.e. some attributes being
 3 desirable and others being undesirable. In the traditional DFT model, an analyst needs to
 4 make a priori assumptions about this directionality, and failing to correct for the *sign* of the
 5 impact of attributes can have undesired consequences, as illustrated in Table 3 of [Hancock
 6 et al. \(2018\)](#). With our new approach, we no longer require a priori knowledge or assump-
 7 tions about whether an attribute has a positive or negative impact on the likelihood of an
 8 alternative being chosen, as the attribute scaling parameters can be estimated to be either
 9 positive or negative. This not only results in it being possible to take all attributes into ac-
 10 count without any initial adjustments, but would also, in a random coefficients DFT model,
 11 allow for the possibility of different signs for a given parameter across different individuals.
- 12 • Finally, this new scaling method allows for the importance of attributes to be a function of
 13 socio-demographic variables, leading to the possible requirement of alternative specific coef-
 14 ficients for certain attributes, and/or interactions such as income effects. Whilst our previous
 15 work ([Hancock et al., 2018](#)) demonstrated that DFT could incorporate socio-demographics
 16 through adjustments to the attention weights, the new system removes the non-linearity
 17 caused by shifts in $Cov[\mathbf{W}_{ns,\tau}]$. This means that one could, for example, include β -coefficients
 18 that vary substantially across decision-makers.

19 2.2.2.2 Identification of parameters

20 The literature on DFT (and other mathematical psychology models) often lacks crucial details
 21 in relation to model identification. As with any standard choice model, a DFT model requires a
 22 normalisation of location and scale. For DFT, this is a result of the multiplication of the expect-
 23 ation, ξ_τ , and covariance, Ω_τ , by L (see Equation 9, noting that throughout this section we drop
 24 the indices for individual and choice task). This results in only differences between alternatives, in
 25 terms of both expected values and covariances, mattering. In order to estimate the choice proba-
 26 bilities under a DFT model, we require estimates for four ‘process parameters’ (parameters which
 27 have no equivalent measure in a traditional model such as RUM or RRM) which are exclusive to
 28 DFT and inform the process by which alternatives accumulate preference. These are ϕ_1 and ϕ_2 ,
 29 the sensitivity and memory parameters respectively, the number of preference updating steps, τ ,
 30 and the variance of the error term, σ_ε^2 . As the choices we investigate in this paper do not have a
 31 strictly imposed time threshold, we make no assumptions on the relationship between the number
 32 of deliberation steps, τ , and the real world time, t , taken to make the choice.

33 Theoretical identification

34 To study identification, we write the expectation of the preference values after τ deliberation
 35 steps as $\xi_\tau = \mathbf{a} + \mathbf{b}$ and the covariance of the preference values as $\Omega_\tau = c(\overline{d + e})$. Consequently,
 36 we have:

37 • $\mathbf{a} = (\mathbf{I} - \mathbf{S})^{-1}(\mathbf{I} - \mathbf{S}^\tau) \cdot \boldsymbol{\mu}$

38 • $\mathbf{b} = \mathbf{S}^\tau \cdot \mathbf{P}_0$

- 1 • $c = (I - Z)^{-1} (I - Z^\tau)$
 2 • $d = C \cdot \beta \cdot M \cdot \Psi \cdot M' \cdot \beta' \cdot C'$
 3 • $e = \sigma_\varepsilon^2 \cdot I.$

4 An overspecification occurs if we can have two sets of parameters such that exactly the same set of
 5 probabilities are generated for the full set of choice scenarios. This occurs if all means change by
 6 the same amount, or if the means and square root of the covariance matrix are scaled by the same
 7 factor. We thus consider the following three scenarios:

- 8 1. $\mathbf{a}_1 + \mathbf{b}_1 = \delta + \mathbf{a}_2 + \mathbf{b}_2$
 9 2. $\mathbf{a}_1 + \mathbf{b}_1 = (\mathbf{a}_2 + \mathbf{b}_2) \cdot \gamma$
 10 3. $c_1 \overline{(d_1 + e_1)} = (c_2 \overline{(d_2 + e_2)}) \cdot \gamma^2$

11 An overspecification of location could exist if some value δ exists such that scenario 1 holds.
 12 This is a result of the specification of Equation 9, where ξ_τ is multiplied by L , giving a vector of
 13 differences between the expected preference of the chosen alternative and each other alternative.
 14 Consequently, the addition of δ to each preference value results in no change in the value of $L\xi_\tau$.

15 To avoid this overspecification, the simplest solution is to fix one of the alternative specific
 16 constants (asc) in the initial preference matrix \mathbf{P}_0 . Under DFT, adding the same value to each
 17 alternative specific constant results in the same increase in expected preference value for each
 18 alternative when $\phi_2 = 0$ (as this results in the feedback matrix becoming an identity matrix, which
 19 means there is no impact on \mathbf{P}_0 , see Equation 5).

20 An overspecification of scale can exist if some value γ exists such that scenarios 2 and 3 both
 21 hold. This is a result of the probabilities under DFT being calculated with the use of multivariate
 22 normal distributions (see Equation 9). Critically, these scenarios result in $\xi_{\tau,1} = \gamma \cdot \xi_{\tau,2}$ and $\Omega_{\tau,1} =$
 23 $\gamma^2 \cdot \Omega_{\tau,2}$. Then if we have a set of parameters, θ_1 that results in probabilities, Pr_1 :

$$Pr_1 = \int_{\mathbf{X}_1 > 0} \exp [-(\mathbf{X}_1 - \mathbf{\Gamma}_1)' \Lambda_1^{-1} (\mathbf{X}_1 - \mathbf{\Gamma}_1) / 2] / (2\pi |\Lambda_1|^{0.5}) dX, \quad (16)$$

24 with the corresponding parameter values θ_2 resulting in probabilities, Pr_2 :

$$Pr_2 = \int_{\mathbf{X}_2 > 0} \exp [-(\mathbf{X}_2 - \mathbf{\Gamma}_2)' \Lambda_2^{-1} (\mathbf{X}_2 - \mathbf{\Gamma}_2) / 2] / (2\pi |\Lambda_2|^{0.5}) dX, \quad (17)$$

25 we can now simply observe that the substitutions implied by scenarios 2 and 3, $\mathbf{X}_1 = \gamma \cdot \mathbf{X}_2$, $\mathbf{\Gamma}_1 =$
 26 $\gamma \cdot \mathbf{\Gamma}_2$ and $\Lambda_1 = \gamma \cdot \Lambda_2$, result in $Pr_1 = Pr_2$, as the γ terms all drop out of the equation. We thus
 27 obtain two distinct sets of parameters θ_1 and θ_2 that result in the same estimated probabilities of
 28 observing the full set of choices.

1 To avoid this overspecification, we need to understand the situations under which scenarios 2
2 and 3 hold. One example of when this is the case is when:

$$\theta_1 = [\mathbf{w}, \boldsymbol{\beta}_{DFT}, \mathbf{P}_0, \phi_1, \phi_2, \tau, \sigma_\varepsilon^2] \quad (18)$$

3 and:

$$\theta_2 = [\mathbf{w}, \gamma \cdot \boldsymbol{\beta}_{DFT}, \gamma \cdot \mathbf{P}_0, \phi_1/(\gamma^2), \phi_2, \tau, \gamma \cdot \sigma_\varepsilon^2], \quad (19)$$

4 with $\boldsymbol{\beta}_{DFT} = [\beta_1, \beta_2, \dots, \beta_k]$, $\mathbf{w} = [w_1, w_2, \dots, w_k]$ and $\mathbf{P}_0 = [\delta_1, \delta_2, \dots, \delta_n]$. To avoid this overspecifi-
5 cation, we need to fix a parameter such that $\gamma = 1$ and thus $\theta_1 = \theta_2$. In the absence of a priori
6 knowledge on the directionality of the attributes or the directionality of the underlying preferences
7 towards an alternative, the scaling parameters $\beta_1, \beta_2, \dots, \beta_k$ and the alternative specific constants
8 should not be fixed. Furthermore, ϕ_2 could have an estimate of zero, resulting in ϕ_1 having no
9 impact in Equations 18 and 19. Consequently, the safest option⁴ is to fix $\sigma_\varepsilon^2 = 1$.

10 It is easy to see a relationship between these two normalisations of location and scale and
11 their corresponding normalisations in a RUM context.

12 It is also worth noting at this point that whilst in choice-only datasets, the attribute attention
13 weights and attribute scaling parameters may appear to capture the same feature (the relative im-
14 portance of an attribute), these parameters are not theoretically confounded, as they have differing
15 impacts within the calculation of choice probabilities under DFT. The attribute attention weights
16 do not impact the feedback matrix, whilst the attribute scaling parameters do. This is a direct result
17 of setting the distance between alternatives as $D_{ns,ij}^2 = \sum_{k=1}^K (\beta_k \cdot (x_{ns,i,k} - x_{ns,j,k}))^2$ in the definition
18 for the feedback matrix. Additionally, the attribute scaling parameters do not impact $\Psi = Cov[W_\tau]$
19 (the covariance of the attention weights), which is used directly in the calculation of the covariance
20 of the preference values (see Equation 6, in which Ψ impacts Φ). This is instead calculated solely
21 with the estimates for the attribute attention weights. As a result, only a model containing both will
22 have the full flexibility to capture both effects. We test models with both these features in Section
23 3.5.

24 *Empirical identification and restrictions*

25 The process parameters in DFT have important behavioural roles. However, DFT models are
26 routinely estimated on data where the only observed outcome is the choice itself, with little in-
27 formation about the process by which that choice was reached. If such process information was
28 available, analysts could use it as additional indicators (i.e. additional dependent variables) in a
29 joint estimation of process and outcome, and this would help inform the values of these parameters.
30 In the absence of such data however, some of the parameters may become partially confounded.

31 We additionally impose various restrictions to aid empirical identification of parameters under
32 a DFT model. These, together with the restrictions identified in the previous section, are detailed
33 in Table 1.

⁴An analyst should however be aware of the fact that the required stochasticity in a DFT model could be generated by the random attribute attendance alone, meaning that the estimate for $\sigma_\varepsilon^2 = 0$. This would result in the requirement of an alternative normalisation. We explore this possibility in DFT model 3 in Table 4.

TABLE 1 : Restrictions on DFT parameters

No.	Parameter	Description	Restrictions	Reason	Estimated parameter	Relation
1	δ_h	asc for alternative n	=0	Theoretical identification	n/a	n/a
2*	σ_ε^2	error	=1	Theoretical identification	n/a	n/a
3*	β_k	scale for attribute k	fixed	Theoretical identification	n/a	n/a
4**	ϕ_2	decay	=0	Empirical identification	n/a	n/a
5**	ϕ_1	sensitivity	fixed	Empirical identification	n/a	n/a
6	w_i	weights for attributes	$\sum_1^k w_k = 1$	DFT assumption	w_i^*	$w_i = \exp(w_i^*) / \sum_1^k \exp(w_k^*)$
7	w_1	first attribute weight	$w_1^* = 0$	DFT assumption	n/a	n/a
8**	ϕ_1	sensitivity	> 0	DFT assumption	ϕ_1^*	$\phi_1 = \exp(\phi_1^*)$
9	τ	preference updating steps	> 1	DFT assumption	τ^*	$\tau = 1 + \exp(\tau^*)$
10*	σ_ε^2	error	≥ 0	Mathematical	σ_ε	$\sigma_\varepsilon^2 = (\sigma_\varepsilon)^2$

*Note that only one of restrictions 2 and 3 should be used, and that restriction 10 should be applied if 2 is not used.

** If the estimate for ϕ_2 is equal to or close to zero, restrictions 4 and 5 may also be required to ensure standard errors can be estimated for the other parameters (with restriction 8 no longer required).

1 Some of these constraints are necessary to avoid identification issues, while others simply
 2 avoid sign issues. The following list details why each restriction is required.

- 3 • (1, 2 and 3) There are two theoretical identifications (restriction 1 and either restriction 2 or
 4 3 in Table 1) detailed in the previous section, applied to avoid a theoretical overspecification.
- 5 • (4 and 5) There is an empirical identification issue as a result of the decay parameter, ϕ_2 . In
 6 case there is no impact for the decay parameter, we obtain a value of ϕ_2 equal to or close to
 7 zero. This results in the sensitivity parameter, ϕ_1 , having no impact on the probabilities of
 8 alternatives, thus resulting in an overspecified model. As a consequence, we try two spec-
 9 ifications of DFT for each dataset in our empirical applications: one with and one without
 10 estimated values for these two feedback parameters (see Tables 4, 5 and 6 in the empirical
 11 applications section of the paper).
- 12 • (6 and 7) A DFT model assumes that a decision-maker attends one attribute at each pref-
 13 erence updating step, which implies that the attribute attention weights must all be positive
 14 and sum to one. Estimation of these attention weights is thus aided through the use of logis-
 15 tic transformations and identification is then ensured by fixing one of the adjusted attribute
 16 attention weights $w_1^* = 0$ (which is required as adding the same value to every w_i^* results in
 17 no change to w_i).
- 18 • (8) An exponential transformation ensures that the sensitivity parameter is positive. This
 19 restriction results in alternatives that are more similar to each other competing more with
 20 each other than alternatives that are less similar, as assumed implicitly by DFT models.
- 21 • (9) The number of preference updating steps must exceed a value of one. This can be also
 22 be solved through the use of an exponential transformation.
- 23 • (10) The noise that is added on at each step to the valence (see Equation 3) is drawn from
 24 a normal distribution with mean 0 and variance σ_ϵ^2 . Consequently, as $\sigma_\epsilon^2 \geq 0$, we instead
 25 estimate the standard deviation, σ_ϵ .

26 2.3. The multi-attribute linear ballistic accumulator model (MLBA)

27 In this section, we first look at the existing implementation of MLBA before making a number of
 28 methodological improvements and finally turning to identification issues. The latter section here
 29 is particularly important given that identifiability issues have been noted for LBA models in the
 30 context of simultaneously modelling choice outcome and response time (Evans, 2020).

31 2.3.1. Existing implementation

32 2.3.1.1 Theoretical model

33 We begin our discussion by focussing on LBA, i.e. the single attribute model. Under LBA,
 34 each alternative has a preference strength that grows linearly towards a threshold (see right panel
 35 in Figure 1). The chosen alternative in an LBA model is the first alternative to pass a threshold

1 value, χ . There are two components to the LBA component of the model; the start points and the
2 drift rates.

3 Start points for each of the alternatives are drawn separately from a uniform distribution
4 $U[0, A]$, where A is estimated. For example, Figure 1 demonstrates what a decision might look
5 like if the start points are drawn from a distribution $U[0, 2]$. A different value A_j could be esti-
6 mated for each alternative j , although it is common practice (Trueblood et al., 2014) to assume
7 that all alternatives have starting values that are drawn using the same estimate A . We thus also
8 assume that the same value A is used for each alternative, in both the theoretical identification
9 (2.3.2.3) and the applications of MLBA in this paper (3).

10 The differences in the structure of the models in Trueblood et al. (2013a, 2014) illustrate the
11 fact that many forms are possible for the drift rates when the basic LBA is extended to alternatives
12 with multiple attributes. While it is thus reasonable to expect that there might be other suitable drift
13 rate forms beside those of the final MLBA model, we choose to fit versions similar to the main-
14 stream version of MLBA (Trueblood et al., 2014) as this outperforms the first version (described
15 by Trueblood et al. (2013a)) for our choice datasets (see Appendix A).

16 In the original MLBA work (Trueblood et al., 2014), the model translates attribute values into
17 ‘subjective values’. In their example, Trueblood et al. (2014) had two similar attributes: testimony
18 strength of eyewitness P and testimony strength of eyewitness Q. To translate objective values into
19 subjective values, a parameter was introduced such that an ‘indifference curve’ could be calculated
20 to avoid issues of extremeness aversion (Chernev, 2004), where, for example, values of 50-50
21 might be preferred to 70-30. This example is however very different from many real-world choice
22 settings, including travel ones, where the individual attributes are not as closely related. To translate
23 objective attribute values into subjective values in this case, we instead require some measure to
24 translate the values appropriately such that the relative importance of the attributes is accounted for.
25 We achieve this by using attribute importance parameters instead of m , the additional parameter in
26 the original specification of MLBA (Trueblood et al., 2014), with more details in Section 2.3.2.2.

27 MLBA assumes that the drift rate for each alternative is an independent draw from a normal
28 distribution (truncated below zero), where, for individual n , choice task s , and alternative j , we
29 have the drift rate $D_{ns,j}$ given as:

$$D_{ns,j} \sim TN(d_{ns,j}, \sigma_{ns,j,\epsilon}) \quad (20)$$

30 with mean drift rate $d_{ns,j}$ and standard deviation $\sigma_{ns,j,\epsilon}$. Typically, and in all the applications in this
31 paper, the standard deviation is set to be equal across alternatives, individuals and choice tasks, i.e.
32 $\sigma_{ns,j,\epsilon} = \sigma_\epsilon, \forall n, s, j$, but a different value could be estimated for each drift rate (Trueblood et al.,
33 2013b).

34 In the current version of MLBA, mean drift rates follow the specification used by Trueblood
35 et al. (2014):

$$d_{ns,j} = v_{ns,j} + I_0 \quad (21)$$

36 where I_0 is a positive constant (which can be specified such that all drift rates have a positive
37 mean) and $v_{ns,j}$ is a value function, similar to random regret minimisation in that it compares an

1 alternative j against all other alternatives i across each attribute x . Specifically, with K attributes
 2 and J_n alternatives, we have that:

$$v_{ns,j} = \sum_{i \neq j}^{J_n} \sum_{k=1}^K (w_{x_{ns,ij,k}} \cdot (x_{ns,j,k} - x_{ns,i,k})). \quad (22)$$

3 In this notation, $x_{ns,i,k}$ is the objective value for the k^{th} attribute for alternative i , and $w_{x_{ns,ij,k}}$ is a
 4 weight for attribute k and alternative pairing i and j , which relates to the similarity between them,⁵
 5 In particular, the similarity is assumed to be an exponential decaying function of distance, with:

$$w_{x_{ns,ij,k}} = \exp(-\lambda \cdot |x_{ns,i,k} - x_{ns,j,k}|) \quad (23)$$

6 Two different values of λ are used depending on whether the difference between $x_{ns,i,k}$ and $x_{ns,j,k}$
 7 is positive or negative:

$$\lambda = \begin{cases} \lambda_1, & \text{if } x_{ns,j,k} \geq x_{ns,i,k} \\ \lambda_2, & \text{if } x_{ns,j,k} < x_{ns,i,k} \end{cases} \quad (24)$$

8 This feature can capture differences between the subjective similarity between A and B and the
 9 subjective similarity between B and A, which may not be equal (Tversky, 1977), with gains and
 10 losses regularly having been shown to be treated differently in a transport context (Hess et al.,
 11 2008; Masiero and Hensher, 2010; Stathopoulos and Hess, 2012). We consider possible values
 12 and interpretations of these parameters further in Appendix D. Additionally, it is worth noting here
 13 that work by Terry et al. (2015) suggests that the distributional form of LBA has limited impact.
 14 This implies that the formula for the mean drift rates (Equation 22) may be key. We return to this
 15 point in Section 2.3.3.

16 *Calculating choice probabilities*

17 If we have values for the drift rates of the alternatives and for the start point and threshold (A
 18 and χ respectively), we can calculate the probability of each alternative's accumulator being the
 19 first to finish, i.e. for its value function to exceed the threshold χ before any others do (Brown and
 20 Heathcote, 2008).

21 As that the starting evidence is drawn from a uniform distribution $U[0,A]$, the amount of
 22 evidence that needs to be accumulated for an alternative to reach the threshold χ is $U[\chi-A,\chi]$
 23 (assuming $\chi > A$). Given an alternative's drift rate distribution, $D_{ns,j}$, the cumulative distribution
 24 function for the time taken for the accumulator associated with alternative j is:

$$F_{ns,j}(t) = \text{Prob} \left(\frac{U[\chi - A, \chi]}{D_{ns,j}} < t \right). \quad (25)$$

25 Brown and Heathcote (2008) demonstrate that for a mean drift rate following a normal distribu-

⁵Note that Equation 22 is equivalent to Equation 3 in Trueblood et al. (2014) but for objective values rather than subjective values, and with a generalisation to multiple alternatives and multiple attributes.

tion⁶, this reduces to:

$$F_{ns,j}(t) = 1 + \frac{\chi - A - t \cdot d_{ns,j}}{A} \cdot \Phi\left(\frac{\chi - A - t \cdot d_{ns,j}}{t \cdot \sigma_\epsilon}\right) - \frac{\chi - t \cdot d_{ns,j}}{A} \cdot \Phi\left(\frac{\chi - t \cdot d_{ns,j}}{t \cdot \sigma_\epsilon}\right) + \frac{t \cdot \sigma_\epsilon}{A} \cdot \phi\left(\frac{\chi - A - t \cdot d_{ns,j}}{t \cdot \sigma_\epsilon}\right) - \frac{t \cdot \sigma_\epsilon}{A} \cdot \phi\left(\frac{\chi - t \cdot d_{ns,j}}{t \cdot \sigma_\epsilon}\right), \quad (26)$$

where ϕ and Φ are the standardised normal distribution's density and cumulative density functions, respectively. The associated probability density function is then:

$$f_{ns,j}(t) = \frac{1}{A} \left[-d_{ns,j} \cdot \Phi\left(\frac{\chi - A - t \cdot d_{ns,j}}{t \cdot \sigma_\epsilon}\right) + d_{ns,j} \cdot \Phi\left(\frac{\chi - t \cdot d_{ns,j}}{t \cdot \sigma_\epsilon}\right) + \sigma_\epsilon \cdot \phi\left(\frac{\chi - A - t \cdot d_{ns,j}}{t \cdot \sigma_\epsilon}\right) - \sigma_\epsilon \cdot \phi\left(\frac{\chi - t \cdot d_{ns,j}}{t \cdot \sigma_\epsilon}\right) \right]. \quad (27)$$

To then calculate the probability of a given alternative j being chosen⁷, we need to calculate the probability density function of alternative j (given individual n , choice task s , and the set of alternatives CS_{ns}) reaching the threshold χ before all other alternatives $i \in CS_{ns}, i \neq j$:

$$Prob(j|CS_{ns}) = \int_0^\infty F_{ns,j}(t) dt = \int_0^\infty f_{ns,j}(t) \prod_{i \neq j}^{J_n} (1 - F_{ns,i}(t)) dt. \quad (28)$$

2.3.2. New developments

2.3.2.1 Incorporating baseline preferences in MLBA

A key feature of many discrete choice models is the concept of alternative specific constants that capture baseline preferences for specific alternatives. Hancock et al. (2018) discusses in detail how this can be implemented in a DFT model. Here, we extend this to the MLBA model.

In particular, we rewrite Equation 21 as

$$d_{ns,j} = \max(0, \delta_{ns,j} + v_{ns,j} + I_0), \quad (29)$$

where $\delta_{ns,j}$ is an additional alternative specific estimated constant capturing a baseline preference for alternative j given choice set s and individual n . Given that we have case studies where each individual completes each choice task a single time (as a contrast to many typical applications of MLBA), we do not have enough data to estimate context-specific baseline preferences, and thus set $\delta_{ns,j} = \delta_j$. The final adjustment we make is to ensure that each mean drift rate has a minimum value of zero (as opposed to fixing I_0 such that this is the case). The use of truncated normals results in it being possible that adding the same constant to each drift rate can result in some more deterministic choices (when the mean drift rates are negative, for example) as well as some less deterministic choices. Adjusting the mean drift rates such that they are at least zero avoids this and aids the estimation of MLBA. For more details of this, please see Appendix B.

⁶We follow the first adjustment made by Heathcote and Love (2012) to translate this for truncated normals.

⁷For full derivations of Equations 26, 27 and 28, refer to Appendix A of Brown and Heathcote (2008).

1 2.3.2.2 *Incorporating attribute specific weights in MLBA*

2 An additional limitation of the original implementation of MLBA is in the treatment of the dif-
 3 ferent attributes. Firstly, this applies in terms of directionality, noting that λ_1 is used for a positive
 4 difference between objective values $x_{ns,i,k}$ and $x_{ns,j,k}$ independently of whether an increase in at-
 5 tribute x_k increases or decreases the attractiveness of an alternative. This limitation is analogous to
 6 the issue with using weight parameters in DFT and would require an analyst to a priori change the
 7 sign for undesirable attributes. Secondly, the actual impact of differences between alternatives in
 8 a given attribute x_k is constant across attributes. Whilst one possibility is to use different valuation
 9 and weighting functions (Cohen et al., 2017), Trueblood et al. (2014) suggest that attribute bi-
 10 ases can be dealt with by including attribute-specific ‘bias parameters’, β_k (an approach analogous
 11 to the attribute-specific scaling coefficients that we defined for DFT) in Equation 23, which then
 12 becomes:

$$w_{x_{ns,ij,k}} = \exp(-\lambda \cdot \beta_k \cdot |x_{ns,i,k} - x_{ns,j,k}|). \quad (30)$$

13 However, we can relax the limitations of attribute bias and directionality simultaneously by
 14 also making an adjustment to the value function (Equation 22), which now takes the same form
 15 as that of the original specification with the exception that we add in attribute-specific scaling
 16 coefficients, β_k .⁸ This results in the value function from Equation 22 being redefined as:

$$v_{ns,j} = \sum_{i \neq j} \sum_{k=1}^K (w_{x_{ns,ij,k}} \cdot \beta_k \cdot (x_{ns,j,k} - x_{ns,i,k})). \quad (31)$$

17 As with the scaling applied to DFT, this change allows us to also make inferences about the rela-
 18 tive importance of different attributes in MLBA, as well as incorporating interactions with socio-
 19 demographics at the level of individual attributes.

20 2.3.2.3 *Identification of parameters*

21 For the estimation of the probability of choosing alternatives in a MLBA model, we require
 22 estimates for K attribute scaling parameters, J alternative specific drift rate constants (we drop the
 23 indices for individual and choice task in this section) and estimates for six process parameters (A
 24 and χ , the start and threshold parameters respectively, a drift rate constant, I_0 , a parameter for the
 25 standard deviation of the drift rates, σ_ϵ , and similarity parameters λ_1 and λ_2). Whilst different
 26 values for these process parameters could be used for different alternatives, we assume that the
 27 same value is used for each alternative (with the exception of the drift rate constants), for the
 28 applications in this paper and for the purposes of identification in the sections below. MLBA has
 29 closed forms for the choice probabilities and response times. However, using choice-only data
 30 requires a number of restrictions, both theoretical and empirical, to aid and improve estimation.

31 *Theoretical identification*

32 For choice-only data (i.e. where no additional process information is available), the start and

⁸Note that for the applications in this paper, we assume that the values for the λ parameters are fixed across attributes. Equivalently, the coefficients β_k are used in both Equations 30 and 31. We relax this assumption when using this function within choice models based on quantum probability in Hancock et al. (2020).

1 threshold parameters A and χ are perfectly confounded. This is a consequence of the fact that
 2 multiplying A and χ by a scale factor f results in no change in the probabilities with which each
 3 alternative is chosen. Instead, this simply changes the time that alternative j finishes in from t_j
 4 to $f \cdot t_j$. As all alternatives are impacted in the same way, the probability of a given alternative
 5 being chosen is not impacted. This can be demonstrated by multiplying A , χ and t by the factor
 6 f in the cumulative distribution function for the time taken by an accumulator (Equation 25). The
 7 factor f drops out, resulting in identical cumulative distribution functions being given by the set of
 8 parameters $\theta_1 = [A, \chi, t]$ and $\theta_2 = [A \cdot f, \chi \cdot f, t \cdot f]$. Consequently, when integrated over $t = 0 \rightarrow \infty$
 9 (see Equation 28), the resulting probabilities are equal. This means that we need to fix either A or
 10 χ . In the applications in this paper, we choose (in line with previous applications, see [Trueblood](#)
 11 [et al. 2014](#)) to fix $A = 1$.

12 Additionally, the choice probabilities are unchanged if all mean drift rates d_j and the standard
 13 deviation σ_ϵ are multiplied by the same factor, g . This is possible, for example, with the parameter
 14 sets θ_1 and θ_2 :

$$\theta_1 = [\boldsymbol{\beta}_{MLBA}, \boldsymbol{\delta}, A, \chi, \sigma_\epsilon, I_0, \lambda_1, \lambda_2] \quad (32)$$

15 and

$$\theta_2 = [\boldsymbol{\beta}_{MLBA} \cdot g, \boldsymbol{\delta} \cdot g, A, \chi, \sigma_\epsilon \cdot g, I_0 \cdot g, \lambda_1 \cdot (1/g), \lambda_2 \cdot (1/g)], \quad (33)$$

16 with $\boldsymbol{\beta}_{MLBA} = [\beta_1, \beta_2, \dots, \beta_k]$ and $\boldsymbol{\delta} = [\delta_1, \delta_2, \dots, \delta_j]$. As with the previous example for changing start
 17 and threshold parameters, this effect simply changes the time that alternative j finishes in. Again,
 18 all alternatives are impacted in the same way, and thus the choice probabilities remain the same (as
 19 we are integrating over $t = 0 \rightarrow \infty$), with the only change being that each alternative j now takes
 20 $\frac{t_j}{g}$ rather than t_j time to finish. We must then fix either σ_ϵ or one of the drift rates d_j to ensure
 21 identification. As before, we follow [Trueblood et al. \(2014\)](#) in setting $\sigma_\epsilon = 1$.

22 Furthermore, in contrast with RUM models, where the choice probabilities only depend on
 23 the differences between alternative specific constants δ_j (see Equation 29), each mean drift rate
 24 can have a separately identified (alternative specific) constant, as the addition of such constants
 25 make the choices more deterministic. This is a result of each alternative taking less time to finish,
 26 meaning there is less time for the alternatives to ‘overtake’ each other. Consequently, the draw
 27 for the starting point of an alternative has a greater influence on the probability of that alternative
 28 finishing first. Note that if we additionally estimate I_0 (which is desirable as this allows us to
 29 determine whether the baseline preferences for the alternatives differ significantly from each other),
 30 then one of the constants δ_j must be fixed to ensure identification.

31 *Empirical identification and restrictions*

32 We additionally impose various restrictions to aid empirical identification of parameters under a
 33 MLBA model. These, together with the restrictions identified in the previous section, are detailed
 34 in Table 2. The following list details why each restriction is required.

- 35 • (1) As detailed in the section on including baseline preference parameters for the different

TABLE 2 : Restrictions on the parameters within MLBA

No	Parameter	Description	Restrictions	Reason	Estimated parameter	Relation
1	δ_j	asc for alternative j	=0	Theoretical identification	n/a	n/a
2	A	start	=1	Theoretical identification	n/a	n/a
3	σ_ϵ	drift rate standard deviation	=1	Theoretical identification	n/a	n/a
4	λ_1	similarity	≥ 0	MLBA assumption	λ_1^*	$\lambda_1 = \exp(\lambda_1^*)$
5	λ_2	similarity	≥ 0	MLBA assumption	λ_2^*	$\lambda_2 = \exp(\lambda_2^*)$
6	χ	threshold	$\geq A$	MLBA assumption	χ^*	$\chi = A * (1 + \exp(\chi^*))$

1 alternatives (see Section 2.3.2.1), one of these alternative specific constants must be fixed to
2 avoid a theoretical overspecification.

- 3 • (2 and 3) Further theoretical restrictions as discussed in Section 2.3.2.3.
- 4 • (4 and 5) Exponential transformations ensure that the lambda parameters are positive. This
5 is required if the similarity between alternatives is to be a decaying function of distance
6 (Trueblood et al., 2014).
- 7 • (6) A further restriction is required on the value of the threshold, χ , which must be greater
8 than the start parameter (to avoid the possibility that more than one alternative reaches the
9 threshold before any deliberation has taken place).

10 2.3.3. Intermediaries between MLBA and econometric choice models

11 LBA models have four components: start point distributions; thresholds; drift rate distributions;
12 and parametric forms for the parameters (mean, usually) of the drift rate distributions. To date,
13 closed forms have only been derived for uniform start point distributions, where this includes the
14 case of no start point variability. Terry et al. (2015) present closed forms for the choice probabilities
15 generated by several LBA models, each with uniform start point variability, but different drift rate
16 distributions - that is, the probability of an alternative being chosen (Equation 28) can be calculated
17 in closed form for LBA models with distributions other than truncated normals.

18 We now present notation for the general case with no start point variability, before looking at
19 variations of MLBA by changing the value function or the drift rate distribution. Since threshold
20 parameters are included in psychological models (mainly) to deal with response time effects, we
21 set all thresholds to one in this section (see the theoretical discussion of this in the previous section,
22 2.3.2.3).

23 Let n denote the individual; s the current choice task; j an option from the current choice set
24 CS_{ns} for individual n ; and t time. Also, let $f_{ns,j}(t)$ (resp., $F_{ns,j}(t)$) denote the drift rate probability
25 density (resp., cumulative density) function. Then, with no start point variability ($A = 0$) and
26 threshold $\chi = 1$, the time taken for the accumulator associated with alternative j simplifies from
27 Equation 25 to:

$$F_{ns,j}(t) = \text{Prob} \left(\frac{1}{D_{ns,j}} < t \right). \quad (34)$$

28 Then, assuming the drift rate distributions, $D_{ns,i}$, are non-negative or truncated below zero, we
29 obtain that the probability of alternative j being chosen given the set of alternatives CS_{ns} is:

$$\text{Prob}(j|CS_{ns}) = \text{Prob} \left[\frac{1}{D_{ns,j}} = \min_{i \in CS_{ns}} \frac{1}{D_{ns,i}} \right], \quad (35)$$

30 The following class of LBA models is of particular interest because it leads to choice probabilities
31 that satisfy a *context dependent Luce model* (equivalently, a *context dependent multinomial logit*

1 *model*) - see [Marley et al. \(2008\)](#), and below, for definitions. Assume that the $D_{ns,j}$ are indepen-
 2 dently distributed with the form $d_{ns,j} \cdot \Delta_j$ where each $d_{ns,j}$ is non-negative, and for every j , $1/\Delta_j$ is
 3 Fréchet-distributed with shape and scale parameter equal to one - that is, for $r > 0$,

$$Prob\left(\frac{1}{\Delta_j} < r\right) = e^{-\left(\frac{1}{r}\right)}, \quad (36)$$

4 Then the cumulative distribution of the time for the accumulator associated with alternative j to
 5 reach the threshold of 1 has the form: for $t > 0$,

$$F_{ns,j}(t) = Prob\left(\frac{1}{d_{ns,j} \cdot \Delta_j} < t\right), \quad (37)$$

6 [Marley and Regenwetter \(2017\)](#) demonstrates that the use of this distribution combined with
 7 zero start point variability leads to a context-dependent Luce model with:

$$P(j|CS_{ns}) = \frac{d_{ns,j}}{\sum_i^{J_n} d_{ns,i}}, \quad (38)$$

8 where J_n is the number of alternatives and $d_{ns,j}$ is a non-negative mean drift rate for alternative
 9 j that depends on the alternatives in the choice set CS_{ns} . Crucially, this context-dependent Luce
 10 model is equivalent to a context-dependent multinomial logit model ([Marley et al., 2008](#)) if we
 11 define utility $U_{ns,i}$ through: $U_{ns,i} = \log(d_{ns,i})$, $i \in CS_{ns}$.

12 In addition, if we take MLBA's value function (Equation 31) and adjust it such that it becomes
 13 linear (for example, by setting each $w_{x_{ns,i,j,k}} = 1$), we obtain the linear value function

$$\begin{aligned} v_{ns,j} &= \sum_{i \neq j}^{J_n} \sum_{k=1}^K \beta_k \cdot (x_{ns,j,k} - x_{ns,i,k}) \\ &= \sum_{i=1}^{J_n} \sum_{k=1}^K \beta_k \cdot (x_{ns,j,k} - x_{ns,i,k}) \\ &= J_n \sum_{k=1}^K \beta_k \cdot (x_{ns,j,k}) - \sum_{i=1}^{J_n} \sum_{k=1}^K (\beta_k \cdot x_{ns,i,k}). \end{aligned} \quad (39)$$

14 If we now assume an LBA with no start point variability ($A = 0$) and Fréchet-distributed drift
 15 rates, we can use the above value function to define the mean drift rate by mapping $v_{ns,j}$ by a
 16 strictly monotonic increasing function onto the positive reals. In particular, if we define the drift
 17 rate by $d_{ns,j} = \exp(v_{ns,j})$, and note that the second term in the above expression is a constant for
 18 the given choice set CS_{ns} , we obtain the following choice probabilities for option j :

$$P(j|CS_{ns}) = \frac{\exp\left[J_n \sum_{k=1}^K \beta_k \cdot (x_{ns,j,k})\right]}{\sum_{i=1}^{J_n} \exp\left[J_n \sum_{k=1}^K \beta_k \cdot (x_{ns,i,k})\right]}. \quad (40)$$

19 As written, this is a *scale dependent MNL model* when there is a common choice set size across
 20 all choice tasks and individuals; it is a *context dependent MNL model* when there is more than one

1 choice set size (i.e. car availability may vary across individuals and thus J_n would not be a constant
 2 across the dataset). However, by the equivalence of context dependent MNL models and context
 3 dependent Luce models, it is also the latter. In particular, with the former (MNL) interpretation, J_n
 4 is the scale (1/variance) of the generating Gumbel distribution.

5 Table 3 summarises the key difference between the models that we evaluate against each
 6 other. An LBA with Fréchet-distributed drift rates, zero start point variability and the drift rate
 7 function specified by Equation 39 gives us a model equivalent to MNL. The MLBA model that we
 8 test assumes truncated normal drift rate distributions; $A \neq 0$; and weights in the value functions
 9 (Equation 31) to translate from objective to subjective values.

TABLE 3 : Context dependent LBA models

		Drift rate distribution, start point variability	
		Fréchet (Eq.37)	Truncated Normal (Eq.28)
		$A = 0$	$A = 1$
Drift rate function	Eq.31	Specification 1	MLBA
	Eq.39	MNL	Specification 2
	Eq.41	RRM	Specification 3

10 We can also consider a (LBA) model equivalent to [Chorus \(2010\)](#)'s random regret minimisa-
 11 tion model (RRM), with drift rates equal to the exponential of the value function:

$$v_{ns,j} = - \sum_{i \neq j} \sum_{k=1}^{J_n} \sum_{k=1}^K \ln(1 + \exp(\beta_k \cdot (x_{ns,i,k} - x_{ns,j,k}))). \quad (41)$$

12 In Section 3.6, we test whether it is the *drift rate distribution* (i.e. whether we use truncated normal
 13 drift rate distributions or Fréchet-distributed drift rates with start rate parameter $A = 0$) or the *drift*
 14 *rate function* that drives differences between MNL, RRM and MLBA. This test is possible as both
 15 MNL and RRM use Equation 38 to generate probabilities of different alternatives and we look at
 16 three additional specifications with features of both MLBA and MNL/RRM:

- 17 • Specification 1 is effectively a 'context-dependent' logit model. It uses drift rates equal to the
 18 exponential of the value function specified by Equation 31 together with Fréchet distributions
 19 (Equation 37) and zero start point variability.
- 20 • Specification 2 is effectively an MLBA model but with weights $w_{x_{ns,ij,k}} = 1$. It uses truncated
 21 normal distributions and ensures mean drifts that are positive through the use of Equation 29
 22 together with values that are generated by the linear value function (Equation 39).
- 23 • Specification 3: is a multi-attribute LBA which still treats positive and negative attribute
 24 differences differently, but at the cost of no additional parameters. It sets mean drift rates
 25 based on Equations 29 and 41.

1 If our results align with those of [Terry et al. \(2015\)](#), where the type of distribution had lit-
2 tle impact on model fit, and MLBA outperforms MNL and RRM, we would also expect to see
3 specification 1 outperform specifications 2 and 3.

4 **3. EMPIRICAL APPLICATIONS ON REVEALED AND STATED CHOICE DATA**

5 In this section, we present empirical results from testing DFT and MLBA on three different
6 datasets, two from stated choice (SC) surveys and one from a revealed preference (RP) survey,
7 where the latter is the first DFT/MLBA application to RP data. For DFT, we investigate the em-
8 pirical identification points detailed in [Table 1](#). We also evaluate the impact of fixing further
9 DFT/MLBA parameters that are insignificant in the first applications of the models, given that, in
10 the context of choice-only data, some of the process parameters may become unimportant. We also
11 compare the estimation results to typical MNL and RRM models. We finally present an empirical
12 comparison between the different existing specifications of DFT and our proposed new scaling
13 approach, as well as a section testing the impact of different distributions and value functions for
14 LBA, as discussed in [Section 2.3.3](#).

15 The estimation of DFT and MLBA remains a non-trivial computational task even with our
16 methodological developments, and efficient implementation as well as good starting values are
17 essential. In all of our applications, we use the R packages `maxLik` ([Henningsen and Toomet,](#)
18 [2011](#)) and `Apollo` ([Hess and Palma, 2019](#)) for estimation of the likelihood function and the RCPP
19 package together with the Armadillo C++ linear algebra library for fast calculation of the matrices
20 that are required for a DFT model to calculate the choice probabilities. ([Eddelbuettel et al., 2011](#);
21 [Sanderson and Curtin, 2016](#)). Additionally, we use an initial parameter search algorithm based on
22 the heuristic for non-linear global optimisation developed by [Bierlaire et al. \(2010\)](#) in an attempt
23 to reduce the risk of convergence to poor local optima or an excessively long estimation process.

24 **3.1. First stated choice survey**

25 Our first dataset is a subset of the data from the Danish value of time study ([Fosgerau, 2006](#)). This
26 dataset comes from a typical stated choice survey, where 545 participants faced a total of 4,214
27 choices between them. The choices were for car drivers and specifically the choice between two
28 different routes, described only by travel cost (in Danish krone, DKK) and travel time (in minutes),
29 where one route is cheaper, but the other is faster. The aim of such a setup is to understand trade-
30 offs between time and money, leading to estimates of the value of travel time (VTT). While very
31 simplistic in nature, this type of dataset is a useful first step in moving from the abstract settings in
32 mathematical psychology towards more complex choices in a transport setting. In all models, we
33 focussed on the time and cost attributes after earlier results confirmed there was no left-right bias
34 that would require the inclusion of alternative specific constants.

35 [Table 4](#) shows the results for this dataset. Where appropriate, we used the constraints from
36 [Table 2](#) but then report the actual transformed estimates in [Table 4](#), along with the transformed
37 standard errors, obtained using the Delta method (cf. [Daly et al., 2012](#)).

1 We first have two MNL models. We initially have a purely linear specification, with the utility
2 for alternative j for individual n in choice task s is:

$$3 \quad U_{nsj} = \delta_j + \beta_{TT} \cdot TT_{nsj} + \beta_F \cdot F_{nsj} + \varepsilon_{nsj}, \quad (42)$$

4 where the β parameters are taste coefficients to be estimated and TT_{nsj} and F_{nsj} give the travel time
5 and fare of the alternative. For the second MNL model, we add terms for the logarithm of time and
6 cost:

$$7 \quad U_{nsj} = \delta_j + \beta_{TT} \cdot TT_{nsj} + \beta_F \cdot F_{nsj} + \varepsilon_{nsj} + \beta_{LTT} \cdot \log(TT_{nsj}) + \beta_{LFF} \cdot \log(F_{nsj}) + \varepsilon_{nsj}. \quad (43)$$

8 This latter model offers a significant improvement in fit over the first model, and all four
9 coefficients remain negative, where the significant estimates for the log-time (β_{LTT}) and log-fare
10 (β_{LFF}) parameters indicate non-linear sensitivities.

11 Whilst a number of different parameters within DFT could be fixed to solve the theoretical
12 overspecification issue identified in Section 2.2.2.2, we follow restriction 2 from Table 1 where a
13 priori information about the other attributes is not required. We initially evaluated different DFT
14 models to test the impact of removing the effect of the feedback matrix (model 2 compared to
15 model 1).

16 The level of competition between alternatives is dependent on their similarity (the Euclidean
17 distance between them) and ϕ_1 . In cases with three or more alternatives, context effects are pre-
18 dicted for certain values of the parameter. When there are only two alternatives (as in the Danish
19 dataset), a significant estimate for ϕ_1 means a reduction in the overall preference for more similar
20 pairs of alternatives, resulting in less deterministic choices. Additionally, ϕ_2 , the memory param-
21 eter, has little meaning when the sequence of attribute attendance is not known. It however also
22 contributes to the level of competition between alternatives as a value of $\phi_2 = 0$ results in the value
23 of ϕ_1 having no impact (see Equation 2). For this dataset, the use of an identity matrix in place of
24 the feedback matrix (model 2) results in an insubstantial loss of model fit. Additionally, we find
25 that if we fix $\sigma_\varepsilon = 0$ (meaning that all of the variation in the DFT model comes from the random
26 attribute attendance), there is again no substantial loss of model fit. Note that with $\sigma_\varepsilon = 0$, we
27 require a further normalisation (see Section 2.2.2.2). Given that we have negative coefficients for
28 the scaling parameters, we follow restriction 3 from Table 4 by setting the first β to -1 . As a
29 consequence of the the noise parameter having an insignificant impact on model fit, fixing it to a
30 value of 1 (as configured in models 1 and 2) results in insignificant parameter estimates for the
31 β -coefficients. By appropriately fixing $\sigma_\varepsilon = 0$ and also fixing the first β , we recover significant
32 parameter estimates elsewhere.

33 Similar to DFT, MLBA has many parameters that have little interpretable output when an an-
34 alyst has choice data, only, and thus no additional psychometric or process data (such as response
35 time). For example, a decision-maker could make a choice quickly because there is a small dif-
36 ference between the start point and threshold or because there is a large difference between one or
37 more drift rates. Consequently, if we only have choice data some of the MLBA parameters become
38 confounded (see Section 2.3.2.3). As with DFT, we initially test MLBA using a full specification,

- 1 which implies only setting the values of the start parameter A and the drift rate standard deviation
- 2 σ_ε to 1.

3 In model 2, we fix the threshold parameter χ , which is a common approach in mathematical
4 psychology (Trueblood et al., 2014; Cohen et al., 2017; Cataldo and Cohen, 2018) (fixing it to a
5 value of 2 as done in the original MLBA paper Trueblood et al. 2014), but find that this is not
6 appropriate in this case, leading to a substantial loss of fit. On the other hand, our initial estimate
7 for λ_1 is so close to zero that fixing it to a value of zero does not lead to any significant loss of
8 fit (model 3). A value of $\lambda_1 = 0$ implies $w_{x_{ns},ij,k} = 1$ resulting in mean drift rates that are linear

1 in the positive differences of attributes $x_{ns,j,k} - x_{ns,i,k}$. Previous work where both λ parameters
 2 approached zero resulted in applications of MLBA resorting to different valuation and weighting
 3 functions (Cohen et al., 2017). In our case, however, only one λ approaches zero, simply meaning
 4 that there is a small amount of non-linear sensitivity to attributes.

5 In terms of model performance using BIC, we see that DFT and MLBA both outperform
 6 MNL. The difference in fit between DFT and MLBA is much smaller than between these two
 7 models and MNL, with a slight advantage for DFT in terms of BIC, and for MLBA in terms of
 8 log-likelihood.

9 3.2. Second stated choice survey

10 The second stated choice dataset we consider has a total of 368 participants, each completing 10
 11 choice tasks resulting in 3,680 choices. The participants are all public transport commuters living
 12 in the UK. Each task involves the choice between an invariant reference trip and two hypothetical
 13 alternatives, where each of the three alternatives is described by travel time (TT in Table 5), fare
 14 (LF), rate of crowded trips, rate of delays (CR and RE , respectively, both out of 10 trips), the
 15 average length of delays (entered into models both as the average extent of delays, RA , and as the
 16 expected delay, RB , by multiplying the length of delays by the rate of delays) and the provision
 17 of a delay information service (none used as the base, with parameters for a charged, ICH , and
 18 free, IFR , service). Following earlier results by Hess and Stathopoulos (2013), we applied a log-
 19 transform to the fare attribute (described as LF).

20 Table 5 shows the results for the second SC dataset. In the presence of three alternatives,
 21 we can now include a RRM model (Chorus, 2010) alongside MNL, where we see fairly similar
 22 performance for these two models, with a slight advantage for MNL. All parameters have the
 23 expected sign in these models, and we are also able to include two alternative specific constants
 24 (ASCs), which results in improvements in log-likelihood of 46 and 61 units respectively for DFT
 25 and MLBA (demonstrating the benefits of the new scaling system for DFT from Section 2.2.2.1
 26 and the new developments for MLBA from Section 2.3.2).

27 For DFT, we follow the same specification tests as on our first SC dataset. However, this time
 28 constraining the feedback matrix to be an identity matrix (as in model 2) leads to a significant
 29 drop in model fit.⁹ This is a direct result of having more than two alternatives, meaning that the
 30 feedback matrix is needed for capturing the different similarities between alternatives.

31 For MLBA, we again show that setting $\chi = 2$ leads to a loss of fit for model 2. Nonetheless, we
 32 can set $\chi = 1$ and $I_0 = 0$ (model 3) without a significant loss of fit. With these constraints, we obtain
 33 larger values for λ_2 than for λ_1 , which means that a greater importance weight is given to positive
 34 attribute differences $x_{ns,j,k} \geq x_{ns,i,k}$ compared to negative ones, $x_{ns,j,k} < x_{ns,i,k}$ in the estimation of
 35 the mean drift rates. This results in subjective differences corresponding approximately to Graph D
 36 in Figure 6: meaning more non-linearity than was observed in SC-1 particularly around differences
 37 close to zero.

⁹Note that in this case, a model with $\sigma_\epsilon = 0$ (as demonstrated to be effective for the first dataset) has a log-likelihood of -3,306.61, thus results in worse fit than a model with $\sigma_\epsilon = 1$.

1 In terms of model performance, we see that each of DFT and MLBA again outperform MNL
 2 and also RRM (which, for this dataset, is not identical to MNL). DFT fits better than MLBA,
 3 potentially because it is better able to deal with the differential competition between the three
 4 alternatives (in contrast to the earlier binary dataset).

5 3.3. RP data

6 Whilst both DFT and MLBA have been applied extensively on experimental data and have been
 7 shown to accurately explain choices in stated preference surveys, we do not know of applications
 8 to revealed preference (RP) data. In this section, we fit MNL, RRM, DFT and MLBA models to
 9 our full RP dataset and provide elasticities as well as out-of-sample predictions.

10 Our RP data comes from the national UK value of travel time study ([Arup, ITS Leeds and](#)
 11 [Accent, 2015](#)). Questionnaires were completed by 2,646 individuals travelling by train from Birm-
 12 ingham, Stoke or Peterborough to London. After extensive data cleaning (see page 164 of [Arup,](#)
 13 [ITS Leeds and Accent 2015](#)), 725 observations were left, with either one or two observations for
 14 each of the 578 individuals. This means we have data that is panel data for some individuals, but
 15 not others. However, this only impacts the calculation of standard errors and does not effect the
 16 results of the models. For every decision recorded, the available alternatives are one or two of
 17 Chiltern railways, Northern rail and Midlands railways as well as one of Virgin Trains and East
 18 Coast. Travel time, travel cost and the time interval between services (headway) were used to
 19 describe the alternatives.

20 We run a basic MNL model with its specification based on the model developed by [Arup, ITS](#)
 21 [Leeds and Accent \(2015\)](#); we estimate different travel time coefficients for each of four groups,
 22 which we now describe. Individuals are first segmented by travel purpose (employees' business,
 23 commute (TT_C in Table 6) or 'other non-work' (TT_O)). Individuals on employees' business where
 24 further segmented into those who were very sure (TT_{EB1}) and those who were quite sure (TT_{EB2})
 25 about the attributes of the unchosen alternatives. We also estimated parameters associated with
 26 travel cost (TC), and headway (HW). For all three attributes, log values are used ([Arup, ITS Leeds](#)
 27 [and Accent, 2015](#)). Additionally, [Arup, ITS Leeds and Accent \(2015\)](#) use three alternative specific
 28 constants for train services run by Chiltern railways (δ_C), Midlands railways (δ_M) and Northern rail
 29 (δ_N). Finally, two parameters are incorporated to capture income effects. Travel time coefficients
 30 (β_{TT_n}) are calculated for each individual n :

$$\beta_{TT_n} = \beta_{TT_{i,n}} \cdot \left(RI_n^{\lambda_{inc}} \cdot (1 - z_{miss,n}) + \lambda_{miss} \cdot z_{miss,n} \right) \quad (44)$$

31 where $\beta_{TT_{i,n}}$ is a travel time coefficient depending on the individual's trip purpose, RI_n is the re-
 32 lative income of the individual, λ_{inc} is an income elasticity on the time sensitivity and λ_{miss} is a
 33 multiplier on the time sensitivity used only if the individual did not provide their income in the
 34 questionnaire (in which case the dummy variable $z_{miss,n} = 1$). Given the developments of the new
 35 scaling system for DFT (Section 2.2.2.1) and scaling parameters for MLBA (Section 2.3.2.2), indi-
 36 vidual travel time coefficients can be estimated equivalently for DFT and MLBA. Table 6 provides
 37 model estimates for these parameters under MNL, RRM, DFT and MLBA.

1 For DFT, we again test two versions. With 118 out of 725 observations having three alter-
 2 natives available and the rest having only two alternatives available, it is unsurprising that, in line
 3 with the results from the first SC dataset, the effect of the feedback parameters being removed
 4 (DFT model 2 relative to DFT model 1) has little impact on the log-likelihood.

5 For MLBA, we see that fixing one of the similarity parameters, λ_2 , to infinity (which results
 6 in the corresponding weight, $w_{x_{ns,ij,k}} = 0$, when $x_{ns,j,k} < x_{ns,i,k}$) has no impact on model fit (model 2
 7 compared to model 1). This implies that the model fits the data well with only positive differences
 8 included in the drift rates. Additionally fixing both I_0 and χ results in an insignificant impact on
 9 model fit with a lower BIC value obtained for model 3 compared to model 2.

10 For the model fit as measured by BIC, MLBA has a lower value than DFT, with both DFT
 11 and MLBA outperforming MNL and RRM.

12 With a view to not just focussing on model fit, Table 7 contrasts the cost and time elasticities
 13 on the RP data for the four models. We see that the elasticities for MNL and RRM are quite similar
 14 to each other. MLBA obtains visibly higher time and cost elasticities than MNL and RRM. For
 15 DFT, the cost and time elasticities are between those for MNL/RRM and MLBA. These results
 16 again show that DFT and MLBA offer more significant departures from standard RUM models
 17 than RRM does.

TABLE 7 : Cost and time elasticities on RP data

	elasticities	
	cost	time
MNL	-0.537	-0.933
RRM	-0.497	-0.933
DFT	-0.604	-1.017
MLBA	-0.670	-1.278

18 We finally test all four models for their ability to make out-of-sample predictions. For each of
 19 the five data subsets, we take choices corresponding to a random 80% of the individuals in the data
 20 to be used for estimation, with the remaining 20% used for validation. We fit each model to each
 21 estimation subset and then calculate log-likelihoods for the remaining 20% of the data using the
 22 parameter estimates obtained for the first 80%. Table 8 gives the log-likelihoods of the estimation
 23 and validation subsets of the data under each model.

24 We see that DFT and MLBA outperform MNL and RRM across all five subsamples in both
 25 estimation and performance on the holdout sample except for DFT in holdout sample 4 and MLBA
 26 in holdout sample 1. MNL outperforms RRM in estimation and holdout across all samples, while
 27 MLBA typically outperforms DFT. Overall, these findings confirm the results on the full sample.

TABLE 8 : Out-of-sample estimation and holdout log-likelihoods for the RP data

	MNL (11 pars)		RRM (11 pars)	
	estimated	forecast	estimated	forecast
Dataset 1	-302.88	-68.92	-303.22	-69.29
Dataset 2	-298.59	-72.76	-298.64	-73.76
Dataset 3	-296.70	-75.08	-295.66	-77.28
Dataset 4	-302.29	-68.18	-303.49	-68.17

1 3.4. Comparison of results

2 3.4.1. Model fit comparisons

3 To summarise the results, Table 9 shows the BIC for the final recommended specification for each
4 model type on each dataset. We see that DFT and MLBA consistently offer better performance
5 than MNL and RRM. While DFT marginally outperforms MLBA on the Danish SC data, the
6 differences are more substantial on the remaining two datasets, with DFT performing best on the
7 UK SC data and MLBA best on the RP data.

TABLE 9 : Model fit (BIC) comparison across models and datasets

	MNL	RRM	DFT	MLBA
Danish (SC-1)	4,465.12	4,465.12	4,057.60	4,061.92
UK (SC-2)	6,802.97	6,809.92	6,706.38	6,743.04
RP	812.54	814.52	805.66	781.49

8 We next consider choice task features that drive the differences in the above model fits. Table
9 10 shows how the difference in the fare between the two alternatives impacts the log-likelihoods
10 of the respective models for the Danish SC dataset. In this case, we observe a clear difference for
11 choice tasks with a difference of less than 1 DKK, with DFT and MLBA outperforming MNL. For
12 larger differences in fare, there are considerably smaller differences in model fit across the models.
13 This suggests that DFT and MLBA perform better than MNL as a result of better predicting choices
14 in situations where the alternatives are more similar to each other. This is also illustrated in Figure
15 2, with the top left panel demonstrating that there are considerably more choice tasks in which the
16 difference in fare is less than 1 DKK (represented by grey crosses) above the grey diagonal line

1 (the latter indicates when DFT and MNL give the same probability). In particular, these choice
 2 tasks have a greater spread of predicted probabilities under a DFT model, again suggesting that
 3 DFT differentiates between similar alternatives more than MNL does.

TABLE 10 : Average log-likelihood contribution per observation in SC-1, with the choice tasks categorised by the difference in fare between the two alternatives.

fare difference (DKK)	number of choice tasks	Dataset (SC-1)		
		MNL-2	DFT-3	MLBA-3
all	4214	-0.525	-0.478	-0.476
0-1	805	-0.531	-0.372	-0.369
1-2	690	-0.641	-0.633	-0.632
2-4	946	-0.599	-0.572	-0.571
4-10	862	-0.504	-0.492	-0.491
10+	911	-0.373	-0.346	-0.340

4 This also appears to be the case for SC-2, with Table 11 showing that there are greater dif-
 5 ferences in the average log-likelihood contribution for choice tasks with smaller fare differ-
 6 ences between the alternatives. However, the difference is less clear cut than for SC-1, with the top right
 7 panel of Figure 2 showing only small differences between MNL and DFT.

TABLE 11 : Average log-likelihood contribution per observation in SC-2, with the choice tasks categorised by the difference in fare between the two alternatives. The choice tasks are categorised by the summed percentage of fare differences between pairs of alternatives.

fare difference	number of choice tasks	Dataset (SC-2)			
		MNL-1	RRM-1	DFT-1	MLBA-3
all	3680	-0.913	-0.914	-0.897	-0.903
0%	127	-1.027	-1.021	-0.977	-1.000
20%	528	-0.941	-0.938	-0.904	-0.920
40%	1425	-0.945	-0.948	-0.928	-0.932
60%	622	-0.874	-0.874	-0.869	-0.874
80%	978	-0.862	-0.864	-0.854	-0.857

8 For the RP dataset, the driver of the difference in model fit is the relative performance on
 9 choice tasks with two or three alternatives. The models have nearly identical log-likelihood con-
 10 tributions for choice tasks with two alternatives (see Table 12). However, DFT and MLBA (in
 11 particular) show much smaller contributions to the overall log-likelihood for choice tasks with
 12 three alternatives. This is also demonstrated in the lower panels of Figure 2, which shows a cluster
 13 of very-well predicted choices especially by MLBA when there are three alternatives.

FIGURE 2 : Comparisons of the predicted probability of the (observed) chosen alternatives under different models for the different datasets. The upper left panel shows a comparison of MNL and DFT for SC-1, with the grey crosses showing choice tasks in which the difference in fare between the alternatives was less than 1 DKK. The upper right panel shows a comparison of MNL and DFT for SC-2, with the grey crosses showing choice tasks where there was no difference in fare across the three alternatives. The lower panels show comparisons of DFT and MLBA against MNL, respectively, for the RP dataset. Grey crosses show choice tasks where there are three alternatives.

1 3.4.2. Model output comparisons

2 We now pay closer attention to the model outputs. An additional benefit of the new scaling method
 3 we use for DFT is that it allows us to more directly compare parameter estimates across different
 4 models, notwithstanding the different meaning of the parameters. This is possible as a result
 5 of the new specifications of both MLBA and DFT having attribute-specific scaling coefficients
 6 (see Sections 2.2.2.1 and 2.3.2.2, respectively), which have a role analogous to marginal utility
 7 coefficients in RUM models. Although these scaling coefficients cannot be directly translated into
 8 measures such as the value of travel time, we can calculate ‘relative importance of travel time

TABLE 12 : Average log-likelihood contribution per observation in the RP dataset, with the choice tasks categorised by whether they have 2 or 3 possible alternatives.

number of alternatives	number of choice tasks	Dataset (RP)			
		MNL-1	RRM-1	DFT-1	MLBA-3
all	725	-0.510	-0.512	-0.501	-0.484
2	607	-0.479	-0.479	-0.479	-0.475
3	118	-0.671	-0.682	-0.617	-0.533

1 with respect to fare’ and make comparisons across models (as long as we ensure that the units
2 are equivalent across models). In Table 13, we set the calculated MNL ratios of time and fare
3 parameters to a base rate of 1 (with the rates being based on the MNL value for commuters in
4 the RP dataset). Consequently we can compare whether DFT and MLBA assign more or less
5 importance to travel time with respect to fare.

TABLE 13 : The relative importance of travel time compared to fare parameter coefficients across different models in comparison to MNL, with standard errors provided in parenthesis (calculated with the Delta method, as discussed by [Daly et al. 2012](#)).

		MNL	RRM	DFT	MLBA
SP	Danish (SC-1)	1.000 (0.047)	1.000 (0.047)	0.774 (0.019)	0.787 (0.035)
	UK (SC-2)	1.000 (0.105)	0.992 (0.103)	0.885 (0.094)	0.685 (0.090)
RP	Commuters	1.000 (0.263)	1.166 (0.300)	1.401 (0.462)	2.678 (1.131)
	Other Non-Work	0.449 (0.174)	0.462 (0.186)	0.649 (0.193)	0.451 (0.131)
	Employees’ Business 1	0.848 (0.180)	0.992 (0.201)	0.992 (0.197)	0.809 (0.330)
	Employees’ Business 2	1.280 (0.173)	1.393 (0.202)	1.661 (0.273)	1.159 (0.465)

6 Across the SP datasets, it appears that MNL tends to assign higher importance to travel time
7 with respect to fare relative to DFT and MLBA, with significant differences found for the Danish
8 dataset. RRM always estimates similar ratios to MNL, while DFT has some similar values to
9 MLBA, with key exceptions being the UK data and commuters in the RP data, for which DFT is
10 more similar to MNL.

11 3.5. DFT model specifications: alternative scaling methods or weights

12 In this section, we compare our new method (see Section 2.2.2.1) to scaling methods that have been
13 used in previous DFT applications, where we do this for both SP datasets. As DFT is scale-variant
14 (see Section 2.2.2.1), a failure to appropriately adjust the attribute values can result in inferior
15 model fit (see Table 5 of [Hancock et al. 2018](#)). Crucially, all previous methods rely on a priori
16 knowledge of the directionality of the attributes, whereas the new method does not. The different
17 scaling methods tested are listed below.

- 1 1. Unity-based normalisation, as used by [Berkowitsch et al. \(2014\)](#), where we rescale the
2 attribute-levels of each attribute, separately, to the range 0 to 1. For an undesirable attribute
3 k , which has value $x_{i,k}$ for alternative i and a set of values X_k across the alternatives in all
4 choice sets in the dataset, we define a normalised attribute value $x'_k = 1 - \frac{x_k - \min(X_k)}{\max(X_k) - \min(X_k)}$,
5 with desirable attribute values being normalised as $x'_k = \frac{x_k - \min(X_k)}{\max(X_k) - \min(X_k)}$.
- 6 2. No scaling method other than taking the negative value for all ‘negative’ attributes (as DFT
7 can only capture ‘positive’ effects of attributes as the relative importance weights must be
8 positive - see Section 4.3.1 of [Hancock et al. \(2018\)](#) for an illustration of the results of failing
9 to do this for DFT models)
- 10 3. Standard score normalisation, as previously found to be effective for DFT (see results in
11 [Hancock et al. 2018](#)), where for undesirable attribute k , which has value $x_{i,k}$ for alternative i
12 and a set of values X_k across the alternatives in all choice sets in the dataset, we define new
13 attribute values $x'_k = -\frac{x_k - \text{mean}(X_k)}{sd(X_k)}$. For desirable attributes, $x'_k = \frac{x_k - \text{mean}(X_k)}{sd(X_k)}$.
- 14 4. Minimum rescaling (dividing each attribute by the smallest value for that attribute across the
15 choice set), as previously shown to be effective for a previous version of MLBA ([Trueblood
16 et al., 2013a](#))
- 17 5. Maximum rescaling (dividing each attribute by the largest value for that attribute across the
18 choice set), as previously shown to be effective for a previous version of MLBA ([Trueblood
19 et al., 2013a](#))
- 20 6. The new method detailed in Section [2.2.2.1](#), which removes the scale-variant nature of DFT.
- 21 7. The new method detailed in Section [2.2.2.1](#), with estimated values for attribute scaling coef-
22 ficients and attribute importance weights.

23 To estimate the models, we require attribute matrices M_{ns} and attention weights w_k and scaling
24 parameters β_k for attribute k . For methods 1-5, M_{ns} is adjusted depending on the method, w_k are
25 estimated and β_k are fixed to a value of 1. For scaling method 6 and 7, M_{ns} is unchanged and β_k
26 are estimated. The weights w_k are fixed to $1/K$ (where K is the number of attributes) for scaling
27 method 6, but are estimated for scaling method 7. All models adhere to the model identification
28 restrictions detailed in Table 1.

29 For both datasets, it appears that our new method (model 6 in Table 14) has the best model
30 fit if either the scales or the weights are fixed parameters. This result holds regardless of whether
31 we include DFT’s feedback matrix. Scaling method 6 appears to better capture the impact of the
32 feedback matrix for the UK data, resulting in an improvement of 27 log-likelihood units, whereas
33 this improvement is much smaller with the other scaling methods corresponding to models 1-5. On
34 the other hand, with the Danish data, the feedback matrix is needed for some of the other scaling
35 methods to obtain model fit more in line with the new scaling. Whilst these results support the
36 incorporation of our new scaling method in DFT, the log-likelihood gain here is dataset-dependent.
37 This means that the main benefit of incorporating this method relates to model configuration (i.e. a

TABLE 14 : Log-likelihood (LL) and BIC values for DFT models with different types of scaling methods for the two stated choice datasets.

1 priori knowledge of the sign of β -coefficients) rather than the model performance, although further
2 applications across a wider variety of choice contexts are required to test how generalisable this
3 finding is.

4 For both datasets, further improvements in model fit are obtained when both weights and
5 scales are estimated. Whilst this improvement is from just one extra parameter for the Danish
6 dataset, the gain in fit comes at a heavy cost for the UK data, which has 7 extra parameters for a
7 relatively insubstantial gain in model fit (and thus results in a worse BIC). This implies that for
8 basic comparisons of DFT against alternative models, analysts may be better off fixing either the
9 weights or the scales. Finally, these results here additionally demonstrate that scaling methods 4
10 and 5 lead to relatively poor performance for DFT; these results are compatible with the fact that
11 scaling methods 4 and 5 resulted in MLBA outperforming DFT in previous studies (Trueblood
12 et al., 2013a).

13 3.6. LBA model specifications

14 Table 15 shows the log-likelihoods for the models described in Section 2.3.3.

15 In all cases, standard MLBA has the best model fit. However, the good performance of speci-

TABLE 15 : Log-likelihoods of models in between MNL, RRM and MLBA, where F indicates a Fréchet distribution and TN indicates a Truncated Normal.

Model	Distribution	Value Function	Log-likelihood			BIC		
			first SC	second SC	RP	first SC	second SC	RP
Specification 1	F - Eq.37	Eq.31	-2,105.36	-3,326.43	-358.44	4,252.46	6,751.39	802.50
MNL	F - Eq.37	Eq.39	-2,301.25	-3,360.43	-370.05	4,627.54	6,802.97	812.54
RRM	F - Eq.37	Eq.41	-2,301.25	-3,363.91	-371.04	4,627.54	6,809.92	814.52
MLBA	TN - Eq.28	Eq.31	-2,005.92	-3,322.26	-351.23	4,061.92	6,743.04	781.49
Specification 2	TN - Eq.28	Eq.39	-2,185.19	-3,355.14	-366.11	4,412.10	6,808.81	817.84
Specification 3	TN - Eq.28	Eq.41	-2,009.88	-3,348.16	-363.35	4,061.49	6,794.85	812.31

1 fication 1 implies that most of the improvement in model fit for MLBA over MNL and RRM comes
 2 from its value function rather than the form of its drift rate distributions (vis, truncated normal).
 3 This is perhaps unsurprising given that Terry et al. (2015) found little differences in fit between
 4 LBA models with different drift rate distributions. The substantial improvement from Specifica-
 5 tion 3 relative to RRM in the first SC is the one clear exception, where it appears that the choice of
 6 distribution does have a distinct impact. This suggests that the benefits obtained through the use of
 7 MLBA model are dataset-dependent. Whilst in some cases an analyst may wish to only adopt the
 8 value function (Equation 31) for ease of implementation, other cases may require the full model.
 9 These results are also displayed in Figure 3, which demonstrates that more substantial model fit
 10 differences are found for the first SC and RP dataset.

FIGURE 3 : Relative model fit of alternative structures in comparison to MLBA across the three datasets.

1 4. SIMULATED DATA EXPERIMENTS

2 The work in Section 3 has provided initial insights about the potential benefits of DFT and MLBA
 3 compared to more traditional structures. Of course, these results are dataset specific and the ad-
 4 vantages might be a result of the true (and unobserved) data generation process. In this section,
 5 we provide some further evidence based on simulated data, where we have a number of aims. In
 6 particular, we test the impacts of considering choices generated by different models, compare the
 7 ability of the different accumulator models at capturing various complexities in the data, and finally
 8 consider parameter recoverability.

9 4.1. Generation of simulated data

10 We use an efficient design to generate 5,000 mode choice observations where each choice task has
 11 four alternatives (car, air, rail and high-speed rail), each described by travel cost (TC) and travel
 12 time (TT). Additionally, all alternatives other than car have an access time (AT) attribute.

13 We then generate choices for four models: an MNL model, a RRM, a DFT, and an MLBA.
 14 The aim of this exercise is to see how well each model fits data generated by each other model
 15 (including the generating model).

16 For the MNL model, we define the utility a respondent n obtains from alternative j in choice
 17 task s as:

$$U_{nsj} = \delta_j + \delta_{F_j} \cdot z_{F,n} + \beta_{TT} \cdot \alpha_{TT_j} \cdot TT_{nsj} + \beta_{TC} \cdot TC_{nsj} \cdot \alpha_{IE,n} + \beta_{AT} \cdot AT_{nsj} + \varepsilon_{nsj} \quad (45)$$

18 where δ_j and δ_{F_j} are alternative specific constants, with the latter capturing the difference between
 19 male and female participants through the use of an appropriate dummy term, $z_{F,n}$, which takes a
 20 value of 1 if individual n is female. TT_{nsj} is the travel time, TC_{nsj} is the travel cost and AT_{nsj} is
 21 the access time, all for alternative j in choice situation s for respondent n . There are coefficients
 22 for travel cost, access time and mode-specific coefficients for travel time, which are defined as
 23 $\beta_{TT} \cdot \alpha_{TT_j}$. A general value β_{TT} is estimated, with appropriate adjustments applied by multiplying
 24 by α_{TT_j} for mode j (for identification purposes we fix this coefficient for cars, $\alpha_{TT_{car}} = 1$). We
 25 additionally have an income effect, $\alpha_{IE,n}$, which is defined as $\alpha_{IE,n} = \left(\frac{income_n}{2500}\right)^{\alpha_I}$, where $income_n$
 26 is the income for individual n and α_I is an estimated income elasticity.

27 These additional coefficients are simple to add to, and estimate in, the various psychological
 28 choice models. For the DFT simulated dataset, we incorporate underlying preferences by setting
 29 the j^{th} element of $P_{ns,0}$ to $\delta_j + \delta_{F_j} \cdot z_{F,n}$, with this having been effective previously (see results in
 30 [Hancock et al. 2018](#)). The alternative specific travel time coefficients can be included in DFT and
 31 MLBA by multiplication of the attribute values, as we use our new scaling method (see Section
 32 2.2.2.1) which means that these coefficients will have an equivalent impact on the attributes in
 33 DFT and MLBA as they would in a RUM model. Finally, in the MLBA models, we incorporate
 34 alternative specific constants (δ_j) by adding them to the mean drift rates as in Equation 29. All of
 35 the values used for the parameters to generate probabilities for each alternative are given in Table
 36 17.

1 4.2. Results for simulated data

2 For each of the four datasets, We now study how well each model performs on data generated with
 3 a different model, thus giving an indication of the robustness of each model to the underlying data
 4 generation process. Table 16 shows the log-likelihood and BIC values for these comparisons.

TABLE 16 : The log-likelihood and BIC values obtained from models for the simulated datasets

Model	free pars.	dataset							
		MNL		RRM		DFT		MLBA	
		LL	BIC	LL	BIC	LL	BIC	LL	BIC
MNL	13	-4,842.60	9,795.92	-4,773.88	9,658.48	-4,907.49	9,925.70	-4,991.23	10,093.18
RRM	13	-4,853.38	9,817.48	-4,727.57	9,565.86	-4,923.43	9,957.58	-5,007.51	10,125.74
DFT	16	-4,847.94	9,832.16	-4,751.80	9,639.88	-4,853.03	9,842.33	-4,934.57	10,005.42
MLBA	17	-4,845.31	9,835.42	-4,741.07	9,626.92	-4,874.60	9,894.00	-4,930.17	10,005.12

5 The main difference between the RRM and MNL data generating models and the MLBA and
 6 DFT data generating models is that there are parameters for competition between psychologically
 7 similar alternatives in the MLBA and DFT models. From the results, it appears that neither MNL
 8 or RRM can capture this competition effect and thus have worse model fits of these models to the
 9 datasets. This is also suggested by the fact that the removal of DFT’s feedback matrix results in
 10 a loss of 10.28 log-likelihood units for the DFT dataset, but only 0.56 units for the MNL dataset.
 11 Crucially, DFT and MLBA also outperform RRM on the data set generated by the MNL and
 12 outperform MNL for the dataset generated by RRM.

13 These results are highlighted by the comparison in Figure 4 of the fit of each of the four
 14 models to each dataset relative to the fit of the model used for data generation. These comparisons
 15 show, for each data set, that DFT and MLBA show much smaller differences in fit relative to the
 16 model consistent with the data generating process (DGP) than do the MNL and RRM, suggesting
 17 that DFT and MLBA are more robust to potential misspecification. MNL and RRM, by contrast,
 18 perform poorly on the datasets generated by DFT and MLBA, with MNL also having poor fit on
 19 the data generated by RRM.

20 4.3. Recovery of parameters from simulated datasets

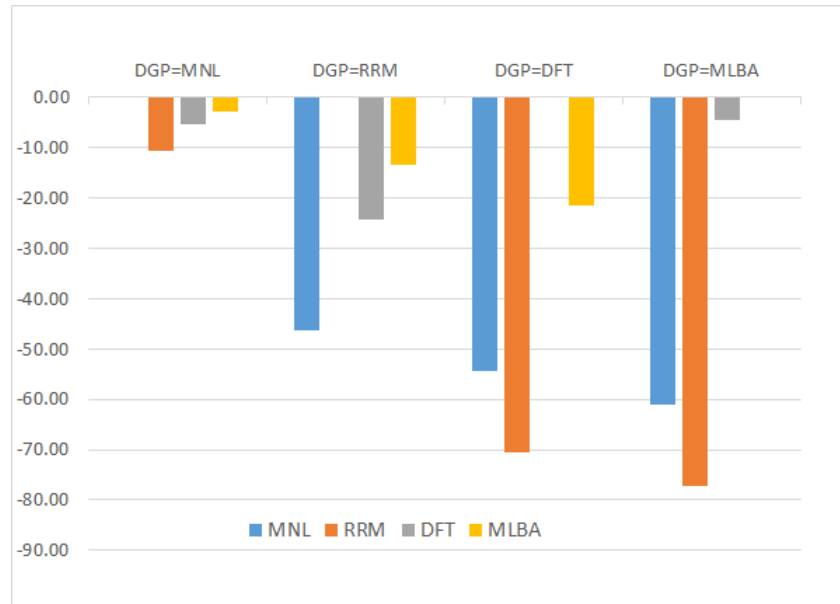

21 We next consider how well the different models recover the parameter values that were used to
 22 generate the simulated datasets for the same model. Table 17 gives the parameters used in sim-
 23 ulating the data (labelled as ‘setup’) as well as the parameters produced in estimation, and the
 24 difference between those two. As each model is tested against a dataset generated by the same
 25 model, we can test the stability of the parameters. Using our new scaling method allows us to use
 26 similar parameter setup values across models, with the exception that parameters are adjusted such
 27 that the data generation process has similar amounts of noise across all datasets no matter which
 28 model is used to generate the choices.

29 All four models appear to accurately recover the three β -coefficients associated with the ex-
 30 planatory variables. These appear to be more recoverable than the alternative specific constants,
 31 which are more susceptible to noise for DFT and MLBA. All four models, however, additionally

TABLE 17 : Parameter values used to generate datasets and estimates for full models for their respective datasets

FIGURE 4 : Log-likelihood of estimated models compared to model consistent with data generating process (DGP)

- 1 perform well at recovering the attribute-specific travel time coefficients. Most importantly for DFT
- 2 and MLBA, the process parameters are fairly well recovered too.

3 5. CONCLUSIONS

4 In this paper, we have considered two alternate accumulator choice models developed in math-
 5 ematical psychology and compared them against models typically used in discrete choice mod-
 6 elling. The models in question are decision field theory (DFT), a model where the preference
 7 strength for each alternative is stochastically updated over time, and the multi-attribute linear bal-
 8 listic accumulator (MLBA), where the preference strength for each alternative increases linearly
 9 and deterministically over time.

10 We first made a number of methodological developments to improve the suitability of the
 11 models for studying travel behaviour and other non-laboratory based choices. For DFT, we imple-
 12 mented a new scaling method on the attributes, which results in a number of benefits such as the
 13 modeller not having to know the sign of the impact of the attributes before running the model. This
 14 has an immediate benefit for the UK dataset, for which one attribute (whether the delay informa-
 15 tion service is free) is a desirable attribute while the other attributes are undesirable. A comparison
 16 with other available scaling approaches in Section 3.5 also highlights the benefits of this approach.
 17 In particular, the new method significantly increases the impact of the feedback matrices on model
 18 fit, although the feedback matrix parameters do not influence model fit when there are only two
 19 alternatives (see the discussion in Section 3.5). However, regardless of whether the feedback ma-
 20 trix has an impact or not, DFT outperforms MNL and RRM for our SP and RP datasets. Whilst
 21 our empirical results suggest that the benefit the new scaling method brings is dataset-dependent,
 22 it is clear that future DFT models should always consider its implementation. This is particularly

1 the case when a researcher does not have a priori information on the directionality of an attribute.
2 However, further research is required to establish the benefits of simultaneously estimating scale
3 and weight parameters.

4 We also considered the impact of including parameters to capture underlying preferences to-
5 wards specific alternatives in MLBA and DFT. Results from our UK dataset suggest that MLBA
6 and DFT make substantial gains when these parameters are included and can consequently capture
7 status quo biases. We have, however, only considered one method for incorporating preferences in
8 these models. Whilst we add parameters to the drift rate in MLBA, alternative specifications would
9 allow for an adjustment of the starting point A or the threshold χ , such that alternatives have differ-
10 ent values for these parameters. It is quite possible that some alternatives may not require as much
11 evidence to be chosen (for example, a commuter's usual route to work), meaning that an MLBA
12 model including alternative specific thresholds may work well. This could be investigated in fu-
13 ture research, with, for example, work on accumulator models with collapsing thresholds already
14 proving popular (Bowman et al., 2012; Hawkins et al., 2015; Evans et al., 2019a). We addition-
15 ally only test MLBA with truncated normal drift rate distributions (with start point variability) and
16 Fréchet-distributed drift rates (with no start point variability, i.e., $A = 0$), while other drift rate
17 distributions could also be considered (Terry et al., 2015). However, results from comparisons of
18 models that have features of MLBA and those that have features of MNL/RRM suggest that the
19 main improvement in model fit for MLBA relative to those standard choice models is due to its
20 value function, and not the form of its (truncated normal) drift rate distributions. This suggests
21 that in some cases, analysts may wish to simply utilise the value function (Equation 31) within a
22 logit model for ease of implementation. Further research is required to understand cases in which
23 moving from this simpler model to MLBA will bring clear advantages, as is the case for our first
24 stated choice study.

25 The operationalisation of the two models in this paper provides promising results and paves
26 the way for the incorporation of data on the processes of decision-making in these models, such as
27 eye-tracking information, response times and EEG data.

28 We also investigate in detail the relative importance of different parameters of our models. In
29 particular, we consider a number of important identification restrictions for both DFT and MLBA.
30 Whilst our theoretical identification requirements in Tables 1 and 2 should always be followed,
31 our results show that the empirical identification issues are dataset-specific. For example, the feed-
32 back matrix in DFT has an impact in only some cases. Additionally, whilst setting the threshold
33 parameter for MLBA to a particular value does not have a significant impact on its fits for our
34 simulated datasets, it does have an impact for our SP data. The opposite is true for the drift rate
35 constant, I_0 , which is important for our simulated datasets but is less important for our SP data. It
36 is possible that the importance of these parameters varies according to how deterministic the data
37 is and further work could test datasets with specified variations in the level of noise. This could
38 help an analyst determine which parameters are important for MLBA for complex choice data.

39 We tested the models extensively using simulated data, where the findings suggest that DFT
40 and MLBA may be less sensitive to model misspecification (i.e. if the estimated model differs
41 substantially from that used for data generation) than the corresponding RUM and RRM models.

1 Crucially, both DFT and MLBA outperform MNL and RRM across the two SP datasets and the
2 RP dataset, including in out of sample validation for the latter, which is to the best of our knowl-
3 edge the first use of either DFT or MLBA on RP data. The good fits of DFT and MLBA to our
4 second stated survey dataset suggest that if there is competition between psychologically similar
5 alternatives (when there are two alternatives that have attributes that are more similar than those of
6 a third alternative), a move towards a choice model with psychological foundations becomes more
7 appealing.

8 Moving away from RUM has obvious pitfalls, especially in terms of the use of models for
9 welfare analysis (see e.g. [Hess et al., 2018](#)). The evidence in this paper suggests that if an analyst is
10 willing to accept these pitfalls, then moving further away from RUM than for example with a RRM
11 model, may be beneficial, and models from mathematical psychology provide an interesting avenue
12 for such work. Of course, more research is needed in terms of additional comparisons, including
13 on larger datasets with more alternatives and attributes. Also, whilst we have considered DFT and
14 MLBA, future research should also consider models from mathematical psychology that do not
15 have closed-form likelihood functions. A large number of models from mathematical psychology
16 such as the drift diffusion model ([Wiecki et al., 2013](#); [Ratcliff et al., 2016](#)), the leaky competing
17 accumulator ([Usher and McClelland, 2001](#)) and the feed-forward inhibition model ([Turner et al.,](#)
18 [2016](#)) can be estimated using hierarchical Bayesian estimation combined with probability density
19 approximation ([Turner and Sederberg, 2014](#)). This means that there is large scope for further
20 comparisons between psychological and mainstream choice models using hierarchical Bayesian
21 estimation, a method already popular in traditional choice modelling for mixed logit models ([Train,](#)
22 [2001](#); [Burda et al., 2008](#); [Dumont et al., 2015](#); [Akinc and Vandebroek, 2018](#)).

23 Additionally, LBA models ([Brown and Heathcote, 2008](#)) have been developed that fit non-
24 stationary data by assuming drift rates that change over time ([Holmes et al., 2016](#)); though with
25 relatively simple stimuli. Similar processes could be added to DFT and MLBA, thus allowing for
26 attributes and/or attribute values that change over time. Such extensions would allow DFT and
27 MLBA to be applied to dynamic revealed preference datasets such as the lane merging decisions
28 made by drivers, where typical choice models may not do so well due to their static nature. Com-
29 plex datasets such as these, as well as datasets with additional process or psychometric measures,
30 would also be useful for further testing the functionality and usefulness of the process parameters
31 within both DFT and MLBA. Additionally, given that in [Hancock et al. \(2018\)](#), we demonstrate
32 that DFT can efficiently incorporate random parameters, it is possible that similar adjustments
33 could also be made for MLBA. All of these potential extensions of DFT and MLBA, combined
34 with the results in this paper, demonstrate that accumulator models such as DFT and MLBA are at-
35 tractive alternative approaches to random utility models, particularly when it comes to forecasting.
36 It therefore appears that these models, as well as others, may hold significant promise in improving
37 the behavioural realism in choice models, in both transport and beyond.

38 ACKNOWLEDGEMENTS

39 The authors acknowledge the financial support by the European Research Council through the con-
40 solidator grant 615596-DECISIONS and funding by the Social Sciences and Humanities Research

1 Council of Canada in the form of Insight grant SSHRC 435-2 to the University of Victoria for
2 Marley. The data used for the revealed preference analysis comes from a study conducted for the
3 UK Department for Transport. The results reported, findings inferred, and views expressed are
4 the responsibility of the authors, and not a statement of the Department's policy or guidance. We
5 would also like to thank Jennifer Trueblood and four anonymous reviewers for their comments on
6 a previous version of this paper.

1 A. APPENDIX: ALTERNATIVE VERSIONS OF MLBA

2 Whilst we use the mainstream version of MLBA (Trueblood et al., 2014) in this paper, it should
 3 be noted that the original version of MLBA (Trueblood et al., 2013a) has also not been tested on
 4 large-scale consumer choice data. Whilst this version of MLBA, here denoted ' $MLBA_0$ ', uses the
 5 same start, threshold and standard deviation for its drift rates, it differs in the specification for the
 6 value of the mean drift rate:

$$d_{ns,j} = \frac{10}{1 + \exp(-\gamma \cdot v_{ns,j})} \quad (46)$$

7 where $v_{ns,j}$ is given by a valence function and γ is a logistic parameter. Small values of the logistic
 8 parameter γ would result in $\exp(-\gamma \cdot v_{ns,j}) \rightarrow 1$, meaning that the valences, $v_{ns,j}$, are less influen-
 9 tial and the probabilities of the alternatives become more similar, resulting in a less deterministic
 10 choice. The valences are similar to a decision field theory model's valences with the exception that
 11 they attempt to additionally capture the comparison process achieved by DFT's feedback matrix.
 12 We thus have

$$V_{ns} = C_{ns} \cdot M_{ns} \cdot \mathbf{W} \quad (47)$$

13 where \mathbf{W} is a vector comprising of a set of attribute importance weights that sum to 1, M_{ns} is the
 14 attribute matrix and C_{ns} is a $J_n \times J_n$ comparison matrix (J_n being the number of alternatives) with
 15 diagonal entries of 1 and off-diagonal elements:

$$C_{ns,i,j \neq i} = \frac{\exp(-\phi \cdot Dist_{ns,i,j}) - 1}{n - 1}. \quad (48)$$

16 Finally, ϕ is a sensitivity parameter such that high values result in the distance between the at-
 17 tributes of the alternatives becoming insignificant. Low values allow for more similar alternatives
 18 to compete more with each other relative to less similar alternatives.

19 Results from applying the previous version of MLBA to both of the SP datasets and the RP
 20 dataset are given in Table 18 below.

TABLE 18 : Comparison of different versions of MLBA

Dataset	$MLBA_0$	MLBA	Difference
Danish	-2,189.78	-2,005.92	-183.86
UK	-3,394.36	-3,322.26	-72.10
RP	-375.24	-351.23	-24.01

21 From these results, it appears that the old version of MLBA has far inferior fits compared to
 22 that of the mainstream MLBA. Consequently, it would appear that modellers should focus on the
 23 mainstream version of MLBA.

1 B. APPENDIX: A MINIMUM MEAN DRIFT RATE

2 Originally, the mean drift rate in MLBA was specified as:

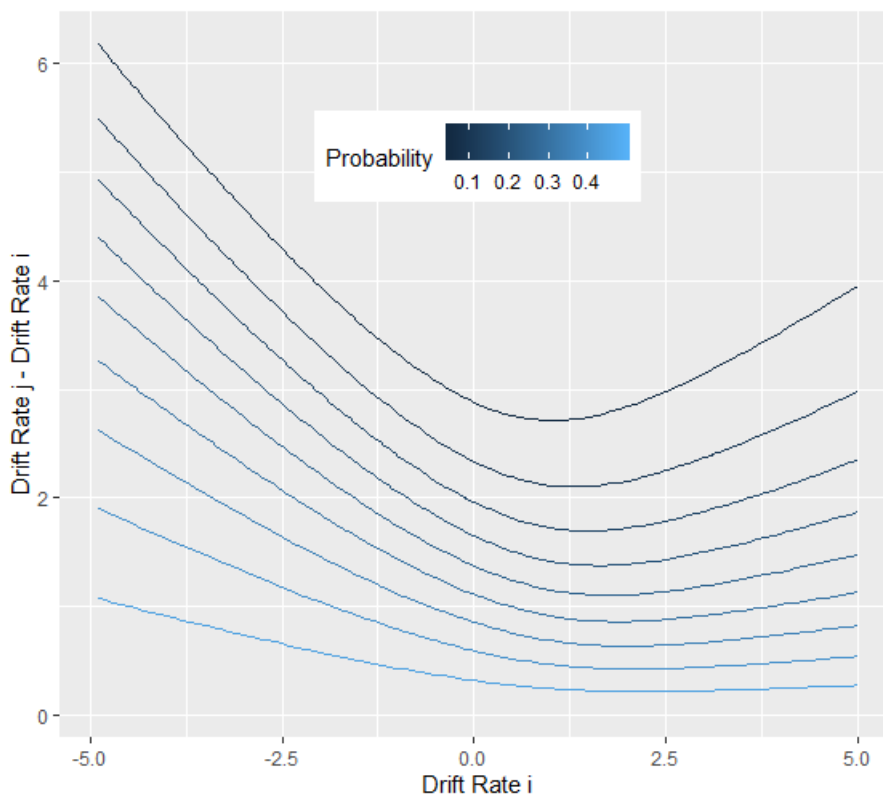

$$d_{ns,j} = v_{ns,j} + I_0. \quad (49)$$

3 As well as choosing to add an alternative specific component here, we also choose to truncate the
4 mean drift rate such that it is always positive:

$$d_{ns,j} = \max(0, \delta_j + v_{ns,j} + I_0), \quad (50)$$

5 To consider the impact of not restricting mean drift rates to be positive, we consider the probabil-
6 ities generated by drift rates i and j where these have values of $-5 < i < 5$ and $i < j < i + 10$.
7 Figure 5 gives the probability of choosing alternative i given the use of these drift rate values as
8 well as values of $A = 1$, $\chi = 2$ and $\sigma_\varepsilon = 1$.

FIGURE 5 : The probability of picking alternative i as the mean drift rate values change

9 In this figure, the contours demonstrate the points at which probabilities remain the same.
10 If these lines were horizontal, it would indicate that for MLBA, only differences in drift rates
11 matter (much as only differences in utility matter in RUM). However, the presence of curved lines
12 indicates that at some points adding I_0 will increase the choice probability of alternative i , whereas
13 it will decrease the probability at other points. This can cause convergence issues for MLBA. We
14 find that fixing the mean drift rates to have a minimum value of zero reduces the impact of this
15 issue and improves estimation of MLBA models.

1 C. APPENDIX: PROOF OF SCALE-INVARIANCE OF DFT WITH SCALING PARAME- 2 TERS

3 Assume a single choice scenario where we have N alternatives each with K attributes. This gives
4 some attribute matrix M_1 . Now suppose we have a set of importance weights \mathbf{w} and scaling values
5 β_{DFT} that give the diagonal matrix β_1 (these could be theoretical values, or based on estimation).
6 To calculate the probability of choosing each alternative, we require the expectation, ξ_τ :

$$\xi_\tau = (I - S)^{-1} \cdot (1 - S^\tau) \cdot C \cdot M_1 \cdot \beta_1 \cdot \mathbf{w} + S^\tau \cdot \mathbf{P}_0, \quad (51)$$

7 and covariance, Ω_τ :

$$\Omega_\tau = (I - Z)^{-1} (I - Z^\tau) \overline{C \cdot M_1 \cdot \beta_1 \cdot \Psi \cdot \beta_1' \cdot M_1' \cdot C' + \sigma_\varepsilon^2 \cdot I}, \quad (52)$$

8 where the expanded forms show us where the attribute matrix M_1 enters the calculations.

9 If we now assume that the attribute matrix is adjusted through the use of, for example, different
10 units for the attributes, we obtain a new matrix, M_2 . Crucially, M_2 can be written as $M_2 = M_1 \cdot$
11 γ , where γ is a matrix created with *dimensional parameters* (see Section 2.2.2.1), arranged in a
12 diagonal matrix such that each attribute k has an associated dimensional parameter γ_k , on the k^{th}
13 diagonal element, which gives the appropriate unit change. With this change, we now have:

$$\xi'_\tau = (I - S)^{-1} \cdot (1 - S^\tau) \cdot C \cdot M_1 \cdot \gamma \cdot \beta_2 \cdot \mathbf{w} + S^\tau \cdot \mathbf{P}_0, \quad (53)$$

14 and:

$$\Omega'_\tau = (I - Z)^{-1} (I - Z^\tau) \overline{C \cdot M_1 \cdot \gamma \cdot \beta_2 \cdot \Psi \cdot \beta_2 \cdot \gamma \cdot M_1' \cdot C' + \sigma_\varepsilon^2 \cdot I}, \quad (54)$$

15 where S , τ , C , \mathbf{w} , \mathbf{P}_0 , Z , σ_ε^2 and Ψ all remain unchanged from Equations 51 and 52.

16 As our new version of DFT includes β_{DFT} scaling parameters, we can set $\xi_\tau = \xi'_\tau$ and $\Omega_\tau =$
17 Ω'_τ simply by setting $\beta_2 = \beta_1/\gamma$. This results in β_{DFT} parameters that correspond to marginal
18 utility parameters in a random utility model, with the probabilities of choosing each alternative
19 unchanged.

20 If we do not have scaling parameters (i.e. $\beta_1 = \beta_2 = I$ in the above equations), DFT becomes
21 scale-variant. This is because the importance weights \mathbf{w} adjust (under estimation) to accommodate
22 the change from M_1 in such a way that the relative importance of the different attributes remains the
23 same. Theoretically, this change would give us a new vector \mathbf{w}' , with elements $w'_i = (w_i/\gamma_i)$.
24 However, there is no guarantee that these new weights satisfy $\sum_1^K w'_k = 1$, as we already have
25 $\sum_1^K w_k = 1$, and the elements of $\gamma \in \mathbb{R}$. More crucially, this changes the value of Ψ (with diagonal
26 elements $\Psi_{ii} = (w_i) \cdot (1 - w_i)$ and off-diagonal elements $\Psi_{ij} = -(w_i) \cdot (w_j)$). The non-linearity of
27 Ψ results in different probabilities being generated should \mathbf{w} change.

28 For example, if we consider the case described in Section 2.2.2.1, we initially have $\mathbf{w} =$
29 $\begin{pmatrix} 0.6 \\ 0.4 \end{pmatrix}$. Incorporating the scale change into the weights instead of the dimensional parameters
30 gives $\mathbf{w}' = \begin{pmatrix} 0.6/1.18 \\ 0.4/60 \end{pmatrix}$. These values however must sum to 1. Multiplying both by a factor of

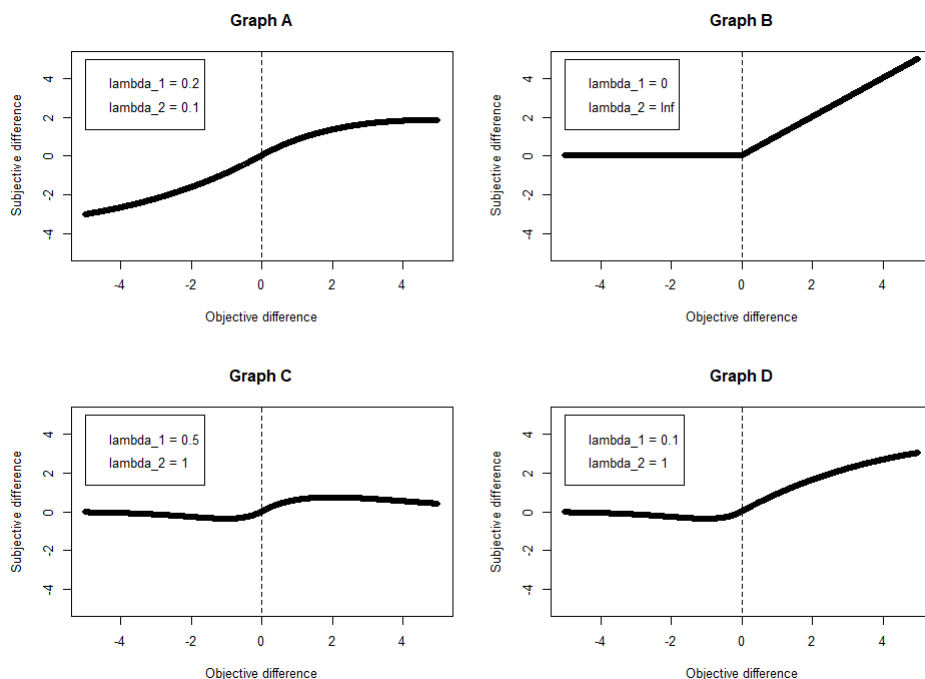

1 1.94 gives $\mathbf{w}'' = \begin{pmatrix} 0.987 \\ 0.013 \end{pmatrix}$. This implies that the time attribute is only considered in 1% of preference updating steps. As a result, the probabilities of choosing the different alternatives changes significantly if there is a low number of preference updating steps. For example, with a single updating step, a slower but cheaper alternative would be chosen with a probability of 60% before the unit change, but 99% after the unit change.

6 **D. APPENDIX: POSSIBLE INTERPRETATIONS OF MLBA PARAMETERS**

7 In this appendix, we consider possible estimated values of the λ parameters in MLBA (Equation 8 24) and how they could be interpreted.

9 In the first case, values of $\lambda_1 = 0.2$ and $\lambda_2 = 0.1$ give us Graph A in Figure 6, which looks 10 similar to a graph of utilities under prospect theory, with decreasing marginal utilities and loss 11 aversion. The ability to capture such effects was the original aim of developing MLBA (Trueblood 12 et al., 2014).

FIGURE 6 : Different possible transformations from objective to subjective differences depending on the value of the lambda parameters under MLBA.

13 However, a key difference here is that MLBA models count each attribute difference between 14 alternatives twice, as each alternative has a separate evaluation of its drift rate (Equation 22 is 15 calculated separately for each alternative). This means that values of $\lambda_1 = 0$ and $\lambda_2 = \infty$ (Graph B) 16 correspond to each difference only being added to one drift rate (linearly) rather than to two drift 17 rates. Additionally, some values of λ result in psychologically unrealistic subjective differences, 18 with for example $\lambda_1 = 0.5$ and $\lambda_2 = 1$ (Graph C) resulting in only certain (close to zero) differences

1 being added to the drift rates. This may be unrealistic if this is the only contribution to drift
2 rates. However, paired individual estimates for the λ parameters may not always be unrealistic-
3 for example, Graph D with $\lambda_1 = 0.1$ and $\lambda_2 = 1$ (which was unrealistic in Graph C) demonstrates a
4 slightly non-linear evaluation of positive objective differences with an extra cost against the worst
5 of two very similar alternatives (through the negative addition to drift rates for very small negative
6 objective differences).

7 As these parameters are also what allows MLBA to capture the similarity effect, it is in appli-
8 cation difficult to establish what features the model may be capturing. Notably, an MLBA model
9 which does not find a similarity effect nor any non-linear sensitivities will result in λ parameters
10 approaching zero. This issue resulted in previous applications of MLBA resorting to different
11 valuation and weighting functions ([Cohen et al., 2017](#)).
